The critical role of calcium ions in the normal contraction of cardiac and vascular smooth muscle is discussed in [Chapters 21 and 49](#). The calcium antagonists (see [Chapter 44](#)) are a heterogeneous group of compounds that inhibit movement of calcium ions through slow channels in cardiac and smooth muscle membranes by noncompetitive blockade of voltage-sensitive L-type calcium channels.¹¹⁴ The three major classes of calcium antagonists are the dihydropyridines (nifedipine is the prototype), the phenylalkylamines (verapamil is the prototype), and the modified benzothiazepines (diltiazem is the prototype). Amlodipine and felodipine are additional dihydropyridines that are among the most commonly used calcium antagonists in the United States. The two predominant effects of calcium antagonists result from blocking the entry of calcium ions and slowing recovery of the channel. Phenylalkylamines have a marked effect on recovery of the channel and thereby exert depressant effects on cardiac pacemakers and conduction, whereas dihydropyridines, which do not impair channel recovery, have little effect on the conduction system.

Mechanism of Action. The efficacy of calcium antagonists in patients with angina pectoris is related to the reduction in myocardial O_2 demand and the increase in O_2 supply that they induce (see [Table 54-4](#)). The latter effect is particularly important in patients with conditions in which a prominent vasospastic or vasoconstrictor component may be present, such as Prinzmetal (variant) angina (see [Chapters 49 and 53](#)), variable-threshold angina, and angina related to impaired vasodilator reserve of small coronary arteries. Calcium antagonists may be effective on their own or in combination with beta blocking agents and nitrates in patients with chronic stable angina. Several calcium antagonists are effective for the treatment of angina pectoris ([Table 54-8](#)). Each relaxes vascular smooth muscle in the systemic arterial and coronary arterial beds. In addition, blockade of the entry of calcium into myocytes results in a negative inotropic effect, which is counteracted to some extent by peripheral vascular dilation and by activation of the sympathetic nervous system in response to drug-induced hypotension.¹¹⁴ However, the negative inotropic effect must be taken into consideration in patients with significant LV dysfunction.

With a rapid onset of action and metabolism by the liver, calcium antagonists have a limited bioavailability of between 13% and 52% and a half-life of between 3 and 12 hours. Amlodipine and felodipine are exceptions in that both drugs have long half-lives and may be administered once daily. In the case of some of the other calcium antagonists (e.g., nifedipine and diltiazem), sustained-release preparations have been shown to be effective.

Antiatherogenic Action. Hyperlipidemia-induced changes in the permeability of smooth muscle cells to calcium may play a role in atherogenesis; thus the hypothesis that calcium antagonists might inhibit atherogenesis has been explored since the 1970s but has not yet achieved consensus.¹¹⁵ Experimental work with calcium channel-blocking drugs, in particular, work with more lipophilic second-generation agents such as amlodipine, has demonstrated improved endothelial function and inhibition of smooth muscle cell proliferation and migration, in addition to ameliorating unfavorable membrane alterations.¹¹⁶ In a randomized trial involving patients with established CAD without hypertension, treatment with amlodipine versus placebo reduced progression of coronary atherosclerosis.¹¹⁵ In a similar trial, nifedipine versus placebo improved coronary endothelial function but did not reduce plaque volume.^{115,116} In summary, although the evidence remains mixed, calcium antagonists may have some role in atheroprotection.

First-Generation Calcium Antagonists

NIFEDIPINE. Nifedipine, a dihydropyridine, is a particularly effective dilator of vascular smooth muscle and is a more potent vasodilator than diltiazem or verapamil. The beneficial effects of nifedipine in the treatment of angina result from its capacity to reduce myocardial O_2 requirements because of its afterload-reducing effect and to

increase myocardial O_2 delivery as a result of its dilating action on the coronary vascular bed (see [Table 54-4](#)). Oral nifedipine in capsule form exerts hypotensive effects within 20 minutes of administration. This immediate-release formulation is no longer recommended because of concerns regarding adverse events. An extended-release formulation should be used when nifedipine is administered. A meta-analysis of 15 studies of long-acting calcium channel antagonists, including nifedipine, in patients with CAD demonstrated a significant reduction in angina, stroke, and heart failure, with similar rates of other cardiovascular outcomes.¹¹⁷ Long-acting nifedipine should be considered an effective and safe antianginal drug for the treatment of symptomatic patients with angina who are already receiving beta-blocking agents, with or without nitrates.

ADVERSE EFFECTS. These occur in 15% to 20% of patients and require discontinuation of medication in approximately 5%. Most adverse effects are related to systemic vasodilation and include headache, dizziness, palpitations, flushing, hypotension, and leg edema (unrelated to heart failure). In rare cases in patients with extremely severe fixed coronary obstructions, nifedipine aggravates angina, presumably by lowering arterial pressure excessively with subsequent reflex tachycardia. For this reason, combined treatment of angina with nifedipine and a beta-blocking agent is particularly effective and superior to nifedipine alone. Nifedipine has been reported to worsen heart failure in patients with preexisting chronic heart failure and is contraindicated in patients who are hypotensive or have severe aortic valve stenosis.

VERAPAMIL. Verapamil dilates systemic and coronary resistance vessels and large coronary conductance vessels. It slows the heart rate and reduces myocardial contractility. This combination of actions results in a reduction in the myocardial O_2 requirement, which is the basis for the drug's efficacy in the management of chronic stable angina ([Table 54-8](#)). When evaluated in INVEST (International Verapamil-Trandolapril Study), a strategy combining sustained-release verapamil and trandolapril versus atenolol and a diuretic for the treatment of patients with hypertension and CAD, including those with previous MI, showed equivalent outcomes with respect to death, MI, or stroke.^{118,119}

In patients with cardiac dysfunction, verapamil may reduce cardiac output, increase LV filling pressure, and cause clinical heart failure. Verapamil slows the heart rate and AV conduction. Therefore it is contraindicated in patients with preexisting AV nodal disease or sick sinus syndrome, heart failure, and suspected digitalis or quinidine toxicity. Intravenous verapamil should generally not be used together with a beta-blocking agent (given intravenously or orally), nor should a beta-blocking agent be administered intravenously in patients receiving oral verapamil. The bioavailability of verapamil is increased by cimetidine and carbamazepine, whereas verapamil may increase plasma levels of cyclosporine and digoxin.

Adverse effects of verapamil are noted in approximately 10% of patients and are related to systemic vasodilation (hypotension and facial flushing), gastrointestinal symptoms (constipation and nausea), and central nervous system reactions such as headache and dizziness. A rare side effect is gingival hyperplasia, which appears after 1 to 9 months of therapy.

DILTIAZEM. Diltiazem's actions are intermediate between those of nifedipine and verapamil. In clinically useful doses its vasodilator effects are less profound than those of nifedipine, and its cardiac depressant action on the sinoatrial and AV nodes and myocardium is less than that of verapamil. This profile may explain the remarkably low incidence of adverse effects of diltiazem. Diltiazem is a systemic vasodilator that lowers arterial pressure at rest and during exertion and increases the workload required to produce myocardial ischemia, but it may also increase myocardial O_2 delivery. Although this drug causes little vasodilation of epicardial coronary arteries under basal conditions, it may enhance perfusion of the subendocardium distal to a flow-limiting coronary stenosis; it also blocks exercise-induced coronary vasoconstriction.

Major side effects are similar to those of the other calcium channel-blocking agents and are related to vasodilation, but they are relatively infrequent, particularly if the dosage does not exceed 240 mg daily. As is the case with verapamil, diltiazem should be prescribed with

TABLE 54-8 Pharmacokinetics of Some Calcium Antagonists Used for Angina Pectoris

caution for patients with sick sinus syndrome or AV block. In patients with preexisting LV dysfunction, diltiazem may exacerbate or precipitate heart failure.

Diltiazem interacts with other drugs, including beta-blocking agents (causing enhanced negative inotropic, chronotropic, and dromotropic effects), flecainide, and cimetidine (which increases the bioavailability of diltiazem), and diltiazem has been associated with increased plasma levels of cyclosporine, carbamazepine, and lithium carbonate. Diltiazem may cause excessive sinus node depression if administered with disopyramide and may reduce digoxin clearance, especially in patients with renal failure.

Second-Generation Calcium Antagonists

The second-generation calcium antagonists (e.g., nifedipine, isradipine, amlodipine, felodipine) are mainly dihydropyridine derivatives, with nifedipine being the prototypic agent. Considerable experience has also accumulated with nimodipine, nisoldipine, and nitrendipine. These agents differ in potency, tissue specificity, and pharmacokinetics and, in general, are potent vasodilators because of the greater vascular selectivity than seen with the first-generation antagonists (e.g., verapamil, nifedipine, diltiazem).

AMLODIPINE. This agent, which is less lipid soluble than nifedipine, has a slow, smooth onset and ultralong duration of action (plasma half-life of 36 hours). It causes marked coronary and peripheral dilation and may be useful in the treatment of patients with angina accompanied by hypertension. It may be used as a once-daily hypotensive or antianginal agent. In a series of randomized placebo-controlled studies in patients with stable exercise-induced angina pectoris, amlodipine was shown to be effective and well tolerated. In two trials involving patients with established CAD, amlodipine reduced the risk for major cardiovascular events. Amlodipine has little, if any negative inotropic action and may be especially useful in patients with chronic angina and LV dysfunction.

The usual dosage of amlodipine is 5 to 10 mg once daily. Downward adjustment of the starting dose is appropriate for patients with liver disease and the elderly. Significant changes in blood pressure are typically not evident until 24 to 48 hours after initiation. Steady-state serum levels are achieved at 7 to 8 days.

NICARDIPINE. This drug has a half-life similar to that of nifedipine (2 to 4 hours) but appears to have greater vascular selectivity. Nicardipine may be used as an antianginal and antihypertensive agent and requires administration three times daily, although a sustained-release formulation is available for twice-daily dosing in patients with hypertension. For chronic stable angina pectoris, it appears to be as effective as verapamil or diltiazem, and its efficacy is enhanced when combined with a beta-blocking agent.

FELODIPINE AND ISRADIPINE. In the United States, both of these drugs are approved by the U.S. Food and Drug Administration for the treatment of hypertension but not for angina pectoris. One study has documented similar efficacy between felodipine and nifedipine in patients with chronic stable angina. Felodipine has also been reported to be more vascular selective than nifedipine and to have a mild positive inotropic effect as a result of calcium channel agonist properties. Isradipine has a longer half-life than nifedipine and demonstrates greater vascular sensitivity.

Nitrates

Mechanism of Action

The action of nitrates is to relax vascular smooth muscle. The vasodilator effects of nitrates are evident in systemic (including coronary) arteries and veins, but they appear to be predominant in the venous circulation. The venodilator effect reduces ventricular preload, which in turn reduces myocardial wall tension and O₂ requirements. The action of nitrates in reducing preload and afterload makes them useful in the treatment of heart failure (see Fig. 54-2), as well as angina. By reducing the heart's mechanical activity, volume, and O₂ consumption, nitrates increase exercise capacity in patients with IHD, thereby allowing greater total-body workload to be achieved before the angina threshold is reached. Thus in patients with stable

angina, nitrates improve exercise tolerance and time to ST-segment depression during treadmill exercise tests. When used in combination with calcium channel-blocking agents and/or beta-blocking agents, the antianginal effects appear to be greater.¹²⁰

Effects on the Coronary Circulation (See Table 54-4). Nitroglycerin causes dilation of epicardial stenoses. Even a small increase in a narrowed arterial lumen can produce a significant reduction in resistance to blood flow across obstructed segments. Nitrates may also exert a beneficial effect in patients with impaired coronary flow reserve by alleviating the vasoconstriction caused by endothelial dysfunction of resistance vessels.

Redistribution of Blood Flow. Nitroglycerin causes blood flow to be redistributed from normally perfused segments to ischemic areas, particularly in the subendocardium. This redistribution may be mediated in part by an increase in collateral blood flow and in part by lowering of LV diastolic pressure, thereby reducing subendocardial compression. Nitroglycerin appears to reduce coronary vascular resistance preferentially in viable myocardium with ischemia, as detected by SPECT. In patients with chronic stable angina responsive to nitroglycerin, topical nitroglycerin under resting conditions alters myocardial perfusion by preferentially increasing flow to areas of reduced perfusion, with little or no change in global myocardial perfusion.

Antithrombotic Effects. Stimulation of guanylate cyclase by nitric oxide (NO) results in inhibitory action on platelets in addition to vasodilation.¹²¹ Although the antithrombotic effects of intravenous nitroglycerin have been demonstrated in patients with unstable angina and in those with SIHD, the clinical significance of these actions is not clear.

Cellular Mechanism of Action. Nitrates have the ability to cause vasodilation, regardless of whether the endothelium is intact. After entering the vascular smooth muscle cell, nitrates are converted to reactive NO or S-nitrosothiols, which activate intracellular guanylate cyclase to produce cyclic guanosine monophosphate (cGMP), which in turn triggers smooth muscle relaxation and antiplatelet aggregator effects (Fig. e54-2). Evidence now exists that biotransformation of nitroglycerin occurs via mitochondrial aldehyde dehydrogenase and that inhibition of this enzyme may contribute to the development of tolerance.¹²² Subsequent studies have also shown cytosolic bioactivation by aldehyde dehydrogenase-2.¹²³ Although the aggregate evidence supports release of NO as the major cellular mechanism of action of oral nitrates, experimental data have raised challenges to this conclusion. In particular, the arterial vasodilatory effects of nitroglycerin in vitro depend at least in part on endothelial calcium-activated potassium channels.

Potential for Adverse Effects During Long-Term Administration. Experimental data have raised questions regarding the potentially competing long-term effects of oral nitrates.¹²² Multiple animal experiments and at least one human study have demonstrated that extended exposure to nitrates can impair endothelial-dependent vasodilation through increases in endothelin-1 and the generation of free radical species. This effect appears to be reversed by antioxidant therapy. Long-term studies in humans are necessary to determine the clinical relevance of these findings.¹²²

Types of Preparations and Routes of Administration

Short-acting nitroglycerin administered sublingually (either by tablet or spray) remains the drug of choice for the treatment of acute angina episodes and for prevention of angina (Table 54-9). Because sublingual administration avoids first-pass hepatic metabolism, a transient but effective concentration of the drug rapidly appears in the circulation. Within 30 to 60 minutes, hepatic breakdown has abolished the hemodynamic and clinical effects. Sublingual nitroglycerin is especially useful when taken prophylactically shortly before undertaking physical activities that are likely to cause angina. When used for this purpose, it may prevent angina for up to 40 minutes.

ADVERSE REACTIONS. Adverse reactions are common and include headache, flushing, and hypotension. The last is rarely severe, but in some patients with volume depletion and in an upright posture, nitrate-induced hypotension is accompanied by a paradoxical bradycardia, consistent with a vasovagal or vasodepressor response. This reaction is more common in older adults, who are less able to tolerate hypovolemia, and may be magnified in hot weather. Methemoglobinemia is a rare complication of very large doses of nitrates; commonly used doses of nitrates cause small elevations in methemoglobin levels that are probably not of clinical significance.

FIGURE e54-2 Mechanism of action of nitrates. Evidence exists that biotransformation of mononitrates occurs through the action of mitochondrial aldehyde reductase in producing NO. NO activates soluble guanylyl cyclase, which results in increased production of cGMP. The second messenger cGMP reduces cytoplasmic calcium (Ca^{2+}) by inhibiting inflow and stimulating mitochondrial uptake of calcium, thus mediating the relaxation of smooth muscle cells and causing vasodilation. Isosorbide dinitrate is metabolized by the liver, whereas the liver is bypassed by mononitrates. GTP = guanosine triphosphate. R-ONO₂ = mononitrate. (Modified from Gori T, Parker JD: Nitrate tolerance: A unifying hypothesis. *Circulation* 106:2510, 2002; and Opie LH: *Drugs for the Heart*. 4th ed. Philadelphia, WB Saunders, 1995, p 33.)

TABLE 54-9 Recommended Dosing Regimens for Long-Term Nitrate Therapy

PREPARATION OF AGENT	DOSE	SCHEDULE
Nitroglycerin*		
Ointment	0.5-2 inches	2-3 times daily
Transdermal patch	0.2-0.8 mg/hr	q24h; remove at bedtime for 12-14 hr
Sublingual tablet	0.3-0.6 mg	As needed, up to 3 doses 5 min apart
Spray	1 or 2 sprays	As needed, up to 3 doses 5 min apart
Isosorbide dinitrate*		
Oral	10-40 mg	2 or 3 times daily
Oral sustained release	80-120 mg	Once or twice daily (eccentric schedule)
Isosorbide 5-mononitrate		
Oral	20 mg	Twice daily (given 7-8 hr apart)
Oral sustained release	30-240 mg	Once daily

*A 10- to 12-hour nitrate-free interval is recommended.

PREPARATIONS

SHORT-ACTING NITROGLYCERIN (NITROGLYCERIN TABLETS AND ORAL SPRAY). Nitrate preparations are available in sublingual, buccal, oral, spray, and ointment forms (Table 54-9). An oral nitroglycerin spray that dispenses metered, aerosolized doses of 0.4 mg may be better absorbed than the sublingual form in patients with dry mucosal membranes. It can also be quickly sprayed onto or under the tongue. For prophylaxis the spray should be used 5 to 10 minutes before angina-provoking activities. An additional advantage of the pump spray preparation is a longer shelf-life (up to 2 years) than that of sublingual nitroglycerin (which is approximately 6 months).

ISOSORBIDE DINITRATE. This drug is available in tablets for sublingual use, in chewable form, in tablets for oral use, and in sustained-release capsules. Partial or complete nitrate tolerance (see later) develops with regimens of isosorbide dinitrate administered as 30 mg three or four times daily. A dosage schedule should be adopted that allows a 10- to 12-hour nitrate-free interval. If the drug is administered on a three-times-daily schedule (e.g., at 8 AM, 1 PM, and 6 PM), the antianginal benefit lasts for approximately 6 hours, and the magnitude of the antianginal benefit decreases with each successive dose.

ISOSORBIDE 5-MONONITRATE. Plasma levels of isosorbide 5-mononitrate reach their peak between 30 minutes and 2 hours after ingestion, and the drug has a plasma half-life of 4 to 6 hours. A single 20-mg tablet still exhibits activity 8 hours after administration. Tolerance has not been demonstrated with once-daily or eccentric dosing intervals but does occur with a twice-daily dosing regimen at 12-hour intervals. The only sustained-release preparation of isosorbide 5-mononitrate is Imdur, which is given once daily at a dosage of 30 to 240 mg. Presumably, this preparation avoids tolerance by providing a sufficiently low nitrate level or a duration of action of 12 hours or less. Once-daily dosing of oral nitrates improves compliance and may offer better efficacy in reducing angina.

TOPICAL NITROGLYCERIN. Nitroglycerin may be applied as a transdermal patch. Application of a silicone gel or polymer matrix impregnated with nitroglycerin results in absorption for 24 to 48 hours at a rate determined by various methods of preparation of the patch. Transdermal nitroglycerin therapy has been shown to increase exercise duration and maintain its anti-ischemic effects for 12 hours after patch application throughout 30 days of therapy, without significant evidence of nitrate tolerance or rebound phenomena, provided that the patch is not applied for more than 12 of 24 hours.

Nitrate Tolerance. A major problem with the use of nitrates is the development of nitrate tolerance, which has been demonstrated with all forms of nitrate administration that deliver continuous, relatively stable blood levels of the drug. Although nitrate tolerance is rapid in onset, renewed responsiveness is easily established after a short nitrate-free interval. The problem of tolerance applies to most nitrate preparations; it is particularly important in patients with chronic angina, as opposed to those receiving short-acting courses of nitrates (e.g., with unstable angina and MI). Nitrate tolerance appears to be limited to capacitance and resistance vessels and has not been noted in large conductance vessels, including the epicardial coronary arteries and radial arteries, despite continuous administration of nitroglycerin for 48 hours.

Mechanisms. Several mechanisms of nitrate tolerance have been proposed. Evidence has supported the hypothesis that increased generation of vascular superoxide anion ($\cdot\text{O}_2^-$) is central to the process.¹²⁴ There are multiple possible contributors to the generation of oxygen free radicals, including the effects of nitroglycerin on eNOS uncoupling and counterregulatory neurohormonal activation. The increased superoxide anion formation has a number of consequences, including plausible links to many of the proposed mechanisms of nitrate tolerance: (1) plasma volume expansion and neurohormonal activation, (2) impaired biotransformation of nitrates to NO, and (3) decreased end-organ responsiveness to NO.¹²⁴

Management. The primary strategy for managing nitrate tolerance is to prevent it by providing a nitrate-free interval. The optimal interval is unknown, but with patches or ointment of nitroglycerin or preparations of isosorbide dinitrate or isosorbide 5-mononitrate, a 12-hour off-period is recommended. Experimental data suggest that nitrate-induced oxidative stress, nitrate tolerance, and endothelial dysfunction may be mitigated by an ARB.¹²⁵ In addition, pentaerythritol tetranitrate is an organic nitrate that may have lesser detrimental effects on mitochondrial aldehyde dehydrogenase.¹²⁶

Nitrate Withdrawal. A common form of nitrate withdrawal (rebound) is observed in patients whose angina is intensified after discontinuation of large doses of long-acting nitrates. In this situation, patients may also have heightened sensitivity to constrictor stimuli. The potential for rebound can be modified by adjusting the dose and timing of administration in addition to the use of other antianginal drugs.

Interaction with Cyclic Guanosine Monophosphate-Specific Phosphodiesterase Type 5 Inhibitors. The combination of nitrates and phosphodiesterase type 5 (PDE5) inhibitors (sildenafil, tadalafil, and vardenafil) may cause serious, prolonged, and potentially life-threatening hypotension.¹⁰⁸ Nitrate therapy is an absolute contraindication to the use of these agents, and vice versa. Patients who wish to take a PDE5 inhibitor should be aware of the serious nature of this adverse drug interaction and be warned about taking any of these agents within 24 hours of any nitrate preparation, including short-acting sublingual nitroglycerin tablets.

Other Pharmacologic Agents

Ranolazine

Ranolazine is a piperazine derivative that was approved in 2006 in the United States for use in patients with chronic stable angina.¹²⁷ Ranolazine is unique among currently approved antianginals in that its anti-ischemic effects are achieved without a clinically meaningful change in heart rate or blood pressure.¹²⁸ When studied at high concentrations in *in vitro* experiments, ranolazine was shown to shift myocardial substrate uptake from fatty acid to glucose and thus was considered to be a potential myocardial metabolic modulator. However, subsequent studies at concentrations of ranolazine consistent with doses tested in clinical trials have indicated that ranolazine exerts favorable effects on ischemia through a reduction in calcium overload in ischemic myocytes via inhibition of the late inward sodium current (I_{Na}).^{129,130} In animal models of ischemia and reperfusion, ranolazine preserves tissue levels of adenosine triphosphate (ATP), improves myocardial contractile function, and reduces the extent of irreversible myocardial injury measured by biomarkers of necrosis and by electron microscopy. Ranolazine has also been suggested to reduce periprocedural myocardial injury in patients undergoing elective PCI.¹³¹

A sustained-release formulation of ranolazine has been studied in three randomized placebo-controlled clinical trials and improved exercise performance and increased the time to ischemia during

FIGURE 54-10 Reduction in the frequency of angina in three randomized, double-blind, placebo-controlled trials of ranolazine in patients with established CAD. Patients with stable CAD and early positive stress testing treated with standard doses of atenolol, amlodipine, or diltiazem were studied in the CARISA (Combination Assessment of Ranolazine In Stable Angina) trial. Patients with stable CAD and at least three episodes of angina per week despite amlodipine, 10 mg daily, were studied in the ERICA (Efficacy of Ranolazine in Chronic Angina) trial. After the diagnosis of non-ST-elevation ACS, patients were studied for an average of 12 months in the MERLIN (Metabolic Efficiency with Ranolazine for Less Ischemia in Non-ST-Elevation Acute Coronary Syndromes) trial. In each trial, ranolazine reduced the frequency of angina. (Data from Chaitman BR, Pepine CJ, Parker JO, et al: Effects of ranolazine with atenolol, amlodipine, or diltiazem on exercise tolerance and angina frequency in patients with severe chronic angina: A randomized controlled trial. *JAMA* 291:309, 2004; Stone PS, Gratsiansky NA, Blokhin A, et al: Antianginal efficacy of ranolazine when added to treatment with amlodipine. *J Am Coll Cardiol* 48:566, 2006; and Morrow DA, Scirica BM, Karwatowska-Prokopczuk E, et al: Effects of ranolazine on recurrent cardiovascular events in patients with non-ST-elevation acute coronary syndromes: The MERLIN-TIMI 36 randomized trial. *JAMA* 297:1775, 2007.)

exercise treadmill testing when used as monotherapy or in combination with the most frequently used doses of atenolol, amlodipine, or diltiazem. Ranolazine also decreases angina frequency and nitroglycerin use when used in conjunction with a beta-blocking agent or calcium channel-blocking agent.¹²⁷

When studied in a randomized, blinded, placebo-controlled trial of 6560 patients with non-ST-segment elevation ACS, ranolazine, administered for an average of approximately 1 year, did not add to standard therapy in secondary prevention of major cardiovascular events. However, ranolazine reduced the incidence of recurrent ischemia, in particular, worsening angina, in a significantly more diverse population with established CAD than studied previously with ranolazine (Fig. 54-10).¹³² Consistent with previous studies, the reduction in angina and improvement in exercise performance were evident only in patients with a history of chronic angina¹³³ and was no less in women than in men.¹³⁴ Because of its proposed mechanism of action on cardiac myocytes rather than modulation of the heart rate or blood pressure, ranolazine has been studied in patients with angina and ischemia without epicardial CAD. In a pilot study of 20 women with angina and no obstructive CAD but with impaired coronary flow reserve on CMR imaging, ranolazine reduced symptoms with evidence of an improved myocardial perfusion reserve index.¹³⁵

The half-life of the sustained-release formulation of ranolazine is approximately 7 hours. A steady state is generally achieved within 3 days of twice-daily dosing. Ranolazine is metabolized primarily through the cytochrome P-450 (CYP3A4) pathway, and thus the plasma concentration is increased if administered in combination with moderate (e.g., diltiazem) or strong (e.g., ketoconazole and macrolide antibiotic) inhibitors of this system. Verapamil increases the absorption of ranolazine by inhibition of P-glycoprotein. Plasma concentrations of simvastatin are increased approximately twofold after the administration of ranolazine, and it should not be coadministered with ranolazine in doses greater than 20 mg daily.

Ranolazine should be started at 500 mg twice daily and may be increased to a maximum of 1000 mg twice daily in patients with persistent angina. The most commonly reported adverse effects in clinical studies are nausea, generalized weakness, and constipation. Dizziness has also been reported, as has a small dose-related increase in the corrected QT (QTc) interval, an average of 2 to 5 milliseconds in the dosage range of 500 to 1000 mg twice daily.

The electrophysiologic effects of ranolazine include inhibition of the delayed rectifier current and inhibition of I_{Na} ; the net effect is to

shorten the action potential duration and suppress early afterdepolarizations.¹³⁶ Thus ranolazine does not have the electrophysiologic profile that has been observed with QT-prolonging drugs associated with torsades de pointes. Rather, ranolazine appears to have clinical electrophysiologic effects on ventricular and atrial arrhythmias. For example, in the randomized trial of 6560 patients with recent ACS noted previously, ranolazine reduced the incidence of arrhythmias detected on ambulatory electrocardiographic monitoring when compared with placebo.¹³⁷ Subsequent experimental and small human studies have revealed possible favorable effects on atrial fibrillation,¹³⁸ suppression of torsades de pointes, and recurrence of internal defibrillator discharges.¹³⁹ Ranolazine remains under investigation for its potential clinical antiarrhythmic effects.¹³⁶ Nevertheless, because of its effect on the QT interval, ranolazine is contraindicated in patients with preexisting QT prolongation, in patients receiving other QT-prolonging medications, or in those with hepatic impairment, which has been associated with a steeper relationship between ranolazine and the QTc.

In addition to these electrophysiologic effects, ranolazine also appears to have glycometabolic effects, including a reduction in hemoglobin A1c, which remains under investigation.^{140,141}

Ivabradine. Ivabradine is a specific and selective inhibitor of the I_f ion channel, the principal determinant of the sinoatrial node pacemaker current.¹⁴² Ivabradine reduces the spontaneous firing rate of sinoatrial pacemaker cells and thus slows the heart rate through a mechanism that is not associated with negative inotropic effects. At this time, ivabradine is investigational in the United States but has been approved in Europe for the treatment of chronic stable angina pectoris in adults in sinus rhythm who are unable to tolerate or have contraindications to beta-blocking agents or in patients inadequately controlled with an optimal dose of a beta blocker and whose heart rate is faster than 60 beats/min. Ivabradine has also been approved in Europe for the treatment of chronic heart failure in combination with standard therapy in patients with a heart rate of 75 beats/min or greater.¹⁴²

Ivabradine reduces the peak heart rate during exercise, increases the time to limiting angina when compared with placebo, and is equivalent to atenolol with respect to exercise performance and time to ischemia (ST-segment depression) in patients with stable angina undergoing exercise treadmill testing.¹⁴³ Ivabradine has also been shown to reduce the heart rate without any effect on ventilator parameters in patients with obstructive pulmonary disease¹⁴⁴ and to be tolerated in patients with CAD and LV dysfunction.¹⁴⁵ In a randomized trial of 10,917 patients with CAD and decreased LV function, ivabradine did not reduce the primary endpoint of cardiovascular death, hospitalization for MI, or hospitalization for heart failure. Fewer hospitalizations for MI were observed in the subgroup of patients with a baseline heart rate greater than 70 beats/min who were randomly assigned to ivabradine versus placebo and in patients with a history of limiting angina.¹⁴⁶ Ivabradine has been shown to reduce cardiovascular death or hospitalization for worsening heart failure in patients with chronic heart failure, reduced ejection fraction, and heart rate of 70 beats/min or higher (see Chapter 25).¹⁴⁷

Nicorandil. Nicorandil is a nicotinamide ester that dilates peripheral and coronary resistance vessels via action on ATP-sensitive potassium channels and possesses a nitrate moiety that promotes systemic venous and coronary vasodilation.¹⁴⁸ As a result of these dual actions, nicorandil reduces preload and afterload and results in an increase in coronary blood flow. In addition to these effects, nicorandil may have

cardioprotective actions mediated through the activation of potassium channels. Nicorandil has been associated with ulcerations of the gastrointestinal tract.

Nicorandil has antianginal efficacy similar to that of beta-blocking agents, nitrates, and calcium channel-blocking agents. In a randomized clinical trial (N = 5126), nicorandil reduced the risk for cardiac death, MI, or hospital admission for angina (hazard ratio [HR], 0.83; $P = 0.014$) in comparison to placebo when added to standard antianginal therapy.

Metabolic Agents. Agents aimed at increasing the metabolic efficiency of cardiac myocytes have also been studied in patients with chronic stable angina. Partial inhibitors of fatty acid oxidation appear to shift myocardial metabolism to more oxygen-efficient pathways. Trimetazidine and perhexiline are drugs that have been shown to inhibit fatty acid metabolism and reduce the frequency of angina without hemodynamic effects in patients with chronic stable angina.^{149,150} These agents remain investigational in the United States but are used clinically in other regions of the world.

Other Considerations of Medical Management of Angina Pectoris

Choice of Initial Therapy

Selection of initial therapy for angina pectoris is reasonably based on an individualized approach to each patient that considers other cardiovascular conditions such as hypertension, tachyarrhythmias, conduction system disease, peripheral artery disease, and LV dysfunction, as well as other non-cardiac-related medical conditions such as severe reactive airways disease, diabetes, or depression. Comparative studies of antianginal agents have not shown any meaningful difference in efficacy to differentiate a specific class of agents for patients with SIHD and no previous MI. Rather, selection of the optimal agent is usually based on overall consideration of the management of coexisting conditions, tolerability, and cost. For most patients, beta-blocking agents or calcium channel antagonists, which are effective and low cost, remain the first line of therapy.

Relative Advantages of Beta-Blocking Agents and Calcium Antagonists (Table 54-10)

The choice between a beta-blocking agent and a calcium channel antagonist as initial therapy in patients with chronic stable angina is controversial because both classes of agents are effective in relieving symptoms and reducing ischemia.¹²⁰ Trials comparing beta blockers and calcium antagonists have not shown any difference in the rate of death or MI,¹²⁰ although in some studies beta blockers appeared to have greater clinical efficacy and less frequent discontinuation because of side effects. Because long-term administration of beta blockers has been demonstrated to prolong life in patients after acute MI (see Fig. 54-7), it is reasonable to consider beta blockers over calcium antagonists as the agents of choice in treating patients with SIHD.^{67,120} Nevertheless, as highlighted by a large observational study, definitive evidence to support this preference is not available (see Fig. 54-7).⁹² In addition, these drugs may produce fatigue, depression, and sexual dysfunction. In contrast, although calcium antagonists do not show these adverse effects, their long-term administration has *not* been shown to improve long-term survival after acute MI.

Selection of Therapy

The choice of drug with which to initiate therapy is influenced by a number of clinical factors (Table 54-10)¹²⁰:

1. In patients with a history of asthma or chronic obstructive lung disease with wheezing on clinical examination, in whom beta-blocking agents, even relatively selective agents, may not be tolerated, calcium antagonists or nitrates are preferred and ranolazine is an option. A trial of a beta blocker should be considered if the patient has a history of previous MI.
2. Nifedipine (long acting), amlodipine, and nicardipine are the calcium antagonists of choice in patients with chronic stable angina and sick sinus syndrome, sinus bradycardia, or significant AV conduction disturbances, whereas beta blockers and verapamil should be used only with great caution in such patients.

TABLE 54-10 Recommended Use of Beta-Blocking Agents or Calcium Antagonists in Patients Who Have Angina in Conjunction with Other Medical Conditions

CLINICAL CONDITION	RECOMMENDED DRUG
Cardiac Arrhythmia or Conduction Disturbance	
Sinus bradycardia	Nifedipine, amlodipine
Sinus tachycardia (not caused by cardiac failure)	Beta-blocking agent
Supraventricular tachycardia	Beta-blocking agent (verapamil)
AV block	Nifedipine or amlodipine
Rapid atrial fibrillation	Verapamil or beta-blocking agent
Ventricular arrhythmia	Beta-blocking agent
Left Ventricular Dysfunction	
Heart failure	Beta-blocking agent
Miscellaneous Medical Conditions	
Systemic hypertension	Beta-blocking agent (calcium antagonist)
Severe preexisting headaches	Beta-blocking agent (verapamil or diltiazem)
COPD with bronchospasm or asthma	Nifedipine, amlodipine, verapamil, or diltiazem
Hyperthyroidism	Beta-blocking agent
Raynaud syndrome	Nifedipine or amlodipine
Claudication	Calcium antagonist
Severe depression	Calcium antagonist

*Alternatives in parentheses.

COPD = chronic obstructive pulmonary disease.

In patients with symptomatic conduction disease, neither a beta blocker nor a heart rate-lowering calcium antagonist should be used unless a pacemaker is in place. If a beta blocker is required in patients with asymptomatic evidence of conduction disease, pindolol, which has the greatest ISA, is useful. In the case of calcium channel-blocking agents in patients with conduction system disease, nifedipine or nicardipine is preferable to verapamil and diltiazem, but careful observation for deterioration of conduction is mandatory. Nitrates and ranolazine are alternatives.

3. Calcium antagonists or long-acting nitrates are clearly preferred for patients with suspected Prinzmetal (variant) angina (see Chapter 53); beta blockers may even aggravate angina under these circumstances.
4. Calcium antagonists may be preferred over beta blockers in patients with significant, symptomatic peripheral arterial disease because the latter may cause peripheral vasoconstriction.
5. Beta-blocking agents should usually be avoided in patients with a history of significant depressive illness and should be prescribed cautiously for patients with sexual dysfunction, sleep disturbance, nightmares, fatigue, or lethargy.
6. The presence of moderate to severe LV dysfunction in patients with angina limits the therapeutic options. The beneficial effects of beta blockers on survival in patients with LV dysfunction after MI, coupled with their beneficial effects on survival and LV performance in patients with heart failure, have established beta-blocking agents as the drug class of choice for the treatment of angina in patients with LV dysfunction, with or without symptoms of heart failure, together with ACE inhibitors, diuretics, and digitalis. If a beta blocker is not tolerated or angina persists despite beta blockade and nitrates, amlodipine can be administered.

Ranolazine is also an option for such patients. Verapamil, nifedipine, and diltiazem should be avoided.

- Hypertensive patients with angina pectoris do well with either beta blockers or calcium antagonists because both have antihypertensive effects. However, beta-blocking agents are the preferred initial drug for treating angina in such patients, as noted earlier, and an ACE inhibitor should strongly be considered for all patients with CAD and hypertension.

Combination Therapy

A combination of multiple agents is widely used for the management of chronic stable angina, with options that include a beta blocker, calcium antagonist, long-acting nitrate, or newer agents such as ranolazine, which may be particularly useful when the heart rate, blood pressure, or LV dysfunction limits escalation of other therapy. In patients with moderate or severe LV dysfunction, sinus bradycardia, or AV conduction disturbances, combination therapy with calcium antagonists and beta blockers should be avoided or should be initiated with caution. The negative inotropic effects of calcium antagonists are not usually a problem in combined therapy with low doses of beta blockers but can become significant with higher doses. With such doses, amlodipine is the calcium antagonist of choice, but it should be used cautiously. Ranolazine may be useful in such patients who do not tolerate other agents. The combination of a dihydropyridine and a long-acting nitrate (without a beta blocker) is not an optimal combination because both are vasodilators.

Synthesis of an Integrated Approach to Management of Patients with Chronic Angina

This approach is as follows:

- Identify and treat precipitating factors, such as anemia, uncontrolled hypertension, thyrotoxicosis, tachyarrhythmias, uncontrolled heart failure, and concomitant valvular heart disease.
- Initiate risk factor modification, physical exercise, diet, and lifestyle counseling. Commence therapy with a high-intensity statin regimen. Historically, such therapy has been aimed at reducing the LDL cholesterol level to a value at least below 100 mg/dL.
- Begin pharmacotherapy with aspirin and a beta blocker. Initiate an ACE inhibitor in all patients with an LV ejection fraction of 0.40 or lower and in those with hypertension, diabetes, or chronic kidney disease. In addition, an ACE inhibitor should be considered for all other patients.
- Use sublingual nitroglycerin for alleviation of anginal symptoms and for prophylaxis, if needed.
- If angina persists, the next step is usually the addition of a calcium antagonist or long-acting nitrate via dosing schedules that prevent nitrate tolerance. The need to treat concomitant hypertension or the presence of LV dysfunction and symptoms of heart failure may be an indication for the use of one of these agents, even in patients in whom episodes of symptomatic angina are infrequent. Ranolazine is an alternative for some patients.
- If angina persists despite two antianginal agents (usually a beta blocker with a long-acting nitrate preparation or a calcium antagonist), add a third antianginal agent. Selection of the agent will be guided by potential side effects and the presence or absence of concomitant hypertension, relative hypotension, conduction system disease, tachyarrhythmias, or LV dysfunction.
- Coronary angiography, with a view to considering coronary revascularization, is indicated in patients with refractory symptoms or ischemia despite optimal medical therapy (OMT). It should also be carried out in patients with high-risk noninvasive test results (see Table 54-3) and in those whose occupations or lifestyles require a more aggressive approach (see also [Revascularization Approaches in Stable Ischemic Heart Disease](#)).

Nonpharmacologic Treatment Approaches. These therapies are generally considered only for patients who have persistent ischemic symptoms after failing medical therapy with multiple agents and coronary revascularization. See [Revascularization Approaches in Stable Ischemic Heart Disease](#).

Enhanced External Counterpulsation. The use of enhanced external counterpulsation (EECP) is another alternative treatment of refractory angina.¹⁵¹ EECP is generally administered as 35 1-hour treatments over a period of 7 weeks. Observational data have suggested that EECP reduces the frequency of angina and the use of nitroglycerin and improves exercise tolerance and quality of life, and responses can last for up to 2 years. In a randomized, double-blind, sham-controlled study of EECP for patients with chronic stable angina, active counterpulsation was associated with an increase in time to ST-segment depression during exercise testing and a reduction in angina, as well as an improvement in health-related quality of life that extended to at least 1 year. There are no definitive data that EECP reduces the extent of ischemia as determined by MPI.

The mechanisms underlying the effects of EECP are poorly understood. Possible mechanisms include the following: (1) durable hemodynamic changes that reduce myocardial O₂ demand; (2) improvement in myocardial perfusion caused by the capacity of increased transmural pressure to open collaterals; and (3) elaboration of various substances that improve endothelial function and vascular remodeling caused by augmented flow through the arterial vascular bed, thereby resulting in an improvement in systemic arterial compliance.¹⁵² Finally, the possibility of placebo effects should be recognized; most of the evidence demonstrating favorable effects of EECP is derived from uncontrolled studies, and data from sham-controlled studies are few.

Spinal Cord Stimulation. An option for patients with refractory angina who are not candidates for coronary revascularization is spinal cord stimulation using a specially designed electrode inserted into the epidural space.^{153,154} The beneficial effects of neuromodulation on pain via this technique are based on the gate theory, in which stimulation of axons in the spinal cord that do not transmit pain to the brain will reduce input to the brain from axons that do transmit pain. Irrespective of the mechanism, several observational studies have reported success rates of up to 80% in terms of reducing the frequency and severity of angina.¹⁵³ One small randomized, sham-controlled study demonstrated an improvement in symptoms and functional status.¹⁵⁵ What is less easily explained is an apparent anti-ischemic effect of this technique. This approach should be reserved for patients in whom all other treatment options have been exhausted.

Transmyocardial Revascularization. See [Other Surgical Procedures for Ischemic Heart Disease](#).

Gene (Angiogenesis) Therapy. See [Chapter 30](#).

Revascularization Approaches in Stable Ischemic Heart Disease (See Chapter 55)

Approach To Decision Making Regarding Revascularization

IHD represents as a dynamic continuum of disease with a variable natural history that may, over decades, encompass many phases of clinical expression ranging from asymptomatic periods, development of chronic exertional angina, subsequent quiescent periods, progression to accelerating angina, and culmination in unstable angina, acute MI, or sudden cardiac death (see [Chapters 39, 51, and 53](#)). Therefore the approach to treatment should be tailored to the individual patient's clinical status. Atherosclerosis is typically a diffuse or multifocal process in which non-flow-limiting coronary stenoses are the principal progenitors of most "hard" clinical events and require a comprehensive systemic approach to management. Moreover, myocardial ischemia may also occur in the absence of obstructive CAD. In general, the principles guiding patient management are predicated on addressing two simultaneous goals, if possible: (1) use of disease-modifying therapies or approaches to prolong life and reduce major cardiovascular events such as acute MI, hospitalization for ACS, or heart failure and (2) optimization of the patient's health status, quality of life, and functional capacity such that angina or ischemia do not have an adverse impact on activities of daily living.¹²⁰

It is widely accepted that the potential benefits of revascularization are proportional to the patient's underlying risk, which makes it essential to quantify the patient's prognosis as accurately as possible (see [Table 54-3](#)). In addition to the patient's risk for major cardiovascular events, sociodemographic factors such as age, physical capacity, ability to adhere to prescribed treatments and lifestyle interventions, overall quality of life, other medical conditions, and patient

preferences should be considered. Each of these aspects should be integrated in considering how to best achieve these fundamental two goals of therapy for patients with SIHD. Revascularization approaches are an integral component of an overall management strategy to improve outcomes and are used when needed in addition to OMT. The success of catheter-based or surgical treatment is predicated on the overall success of guideline-directed secondary prevention and lifestyle intervention as a platform for the management of all patients with SIHD. Decisions regarding the best mode of revascularization (catheter based or surgical) should follow a thoughtful assessment of whether and when revascularization is necessary to achieve these goals of therapy and are best made by a multidisciplinary heart team that includes a noninterventional cardiologist, an interventional cardiologist, and a cardiac surgeon. Patients are also critical participants in decision making in terms of their preferences.¹⁵⁶

Patient Selection for Revascularization

Each of the following considerations may be used to guide decisions regarding the indications for (as well as the approach to) revascularization: (1) the presence and severity of symptoms, (2) physiologic significance of the coronary lesions and other anatomic considerations, (3) extent of myocardial ischemia and the presence of LV dysfunction, and (4) other medical conditions that influence the risks associated with percutaneous or surgical revascularization.

Presence and Severity of Symptoms

A goal of therapy is complete elimination of angina and resumption of full physical function to the extent possible.¹²⁰ Mechanical revascularization (catheter based or surgical) should be considered if ischemic symptoms persist after intensification of medical therapy, including stringent risk factor modification, or if unacceptable side effects or the patient's therapeutic preferences limit antianginal therapy.

Significance of Coronary Lesions (and Other Anatomic Considerations)

Seventy percent or greater stenosis of an epicardial coronary artery is considered to be anatomically significant (≥ 50 for left main coronary stenosis). Thus the professional guidelines that have influenced clinical practice regarding revascularization have been framed principally around these anatomic criteria (number of diseased vessels, extent and severity of anatomic disease), together with integration of functional considerations (magnitude and distribution of ischemia and the amount of threatened myocardium subtending coronary stenosis).^{40,120} Data from a large, prospective randomized trial of PCI versus medical therapy examined the relationship between the severity of stenosis and the extent of angiographic CAD by using quantitative coronary angiography in a core laboratory, and contrary to conventional wisdom, no anatomic subset of CAD stenosis severity (including patients with 70% to 90% narrowing and $>90\%$ narrowing of the LAD coronary artery) was found to benefit from PCI versus medical therapy with respect to long-term clinical events.^{157,158} Moreover, clinicians also fairly commonly face clinical uncertainty regarding the potential significance of "borderline" visual coronary stenoses, nominally defined as lesions in the 50% to 70% range. It is widely acknowledged that angiographically determined stenosis severity expressed as the percentage of luminal narrowing is often an inaccurate measure of a lesion's functional significance.^{2,56} Even though cardiac surgeons have considered 50% or greater stenosis as the criterion for "significant," many factors other than visual stenosis severity (e.g., lesion eccentricity, tortuosity, presence of plaque rupture or asymmetric luminal filling defects, presence of additional serial lesions) can potentially render a 50% to 70% stenosis "functionally or hemodynamically significant." Multiple additional techniques, such as IVUS and other imaging (see Chapter 20), have been shown to provide enhanced assessment of the anatomic and functional significance of specific coronary lesions and may complement stress testing to aid in decision-making judgments regarding the potential benefits of revascularization.

Other anatomic features, in addition to lesion severity, also influence the likelihood of success and the approach to revascularization for a given patient.⁴⁰ Such features include vessel size, extent of calcification, tortuosity, and relationships to side branches (see Chapter 55). Patients with diffuse severe disease of the distal coronary arteries may be poor candidates for any revascularization procedure.

Fractional Flow Reserve (See Chapters 49 and 55).

FFR, which is determined by measuring the pressure or flow distal to a stenosis relative to the pressure or flow before the stenosis (see Figs. 49-13 and 55-1), has proved useful for guiding appropriate decisions regarding revascularization of an intermediate stenosis.⁵⁶ In a study of 325 patients with intermediate stenosis scheduled for PCI, patients with an FFR higher than 0.75 (56%) were randomly assigned to PCI or medical therapy. Patients managed medically had a risk for cardiac death or MI that was less than 1% per year and was not increased relative to the group that underwent stenting.¹⁵⁹ Subsequently, the FFR was evaluated in the FAME (Fractional Flow Reserve versus Angiography for Multivessel Evaluation) trial, in which patients were randomly assigned to conventional, angiographically directed PCI or FFR-guided PCI (with PCI performed only in lesions in which the FFR was 0.8 or less).¹⁶⁰ The results showed a lower 2-year rate of death or MI with the FFR-guided strategy (Fig. e54-3; see also Fig. 49-16). However, the FAME trial did not include a comparison group that received guideline-directed medical therapy without revascularization. The FAME 2 trial, which did include a comparison group receiving guideline-directed medical therapy without revascularization,⁵⁵ is discussed in the section [Comparisons between Percutaneous Coronary Intervention and Medical Therapy](#).

Extent of Ischemia and Presence of Left Ventricular Dysfunction

The four major determinants of risk in patients with CAD are the extent of ischemia, the number of vessels diseased, LV function, and the electrical substrate.⁶ The extent of ischemia on noninvasive testing is an important predictor of subsequent adverse outcomes and identifies patients in whom revascularization may provide clinical benefit over that of medical therapy beyond the relief of symptoms. The major effect of coronary revascularization is on ischemia, and the magnitude of the benefit versus that of medical therapy is enhanced with LV dysfunction, particularly in the presence of reversibly ischemic jeopardized myocardium. Moreover, the greatest survival benefits of CABG, as well as symptomatic and functional improvements, are evident in patients with impaired LV function (generally defined as an ejection fraction <0.40) (Tables 54-11 and 54-12).

Risks Associated with the Procedure

Patients with SIHD more often than not have other medical conditions, such as renal dysfunction, peripheral atherosclerosis, or

TABLE 54-11 Impact of Coronary Artery Bypass Surgery versus Medical Therapy on Survival*

CATEGORY OF RISK	NUMBER OF VESSELS DISEASED	SEVERITY OF ISCHEMIA	EJECTION FRACTION	RESULTS OF SURGERY ON SURVIVAL

*Systematic overview of the effect of CABG versus medical therapy on survival based on data from seven randomized trials comparing a strategy of initial CABG with one of initial medical therapy. Subgroup results at 5 years are shown. From Yusuf S, Zucker D, Peduzzi P, et al: Effect of coronary artery bypass surgery on survival: Overview of 10-year results from randomized trials by the Coronary Artery Bypass Surgery Trialists Collaboration. *Lancet* 344:563, 1994.

pulmonary disease, that may influence the patient's suitability for surgical or percutaneous revascularization. For example, in a patient with peptic ulcer disease and a history of gastrointestinal bleeding, the potential need for long-term dual antiplatelet therapy after a procedure should be considered. Moreover, a patient with three-vessel CAD and impaired LV function who might derive a more durable survival benefit from CABG may be too high risk clinically to undergo surgery and might be a better candidate for multivessel PCI.

In addition, some general principles regarding the choice of treatment in patients with SIHD should be considered:

1. For most patients with chronic angina, revascularization should not constitute the initial management strategy before evidence-based medical therapy (pharmacologic antianginal therapy, disease-modifying treatments, and therapeutic lifestyle intervention) is initiated and optimized.¹²⁰
2. When improvement in survival is not a relevant consideration, the severity of angina or impairment in health status should play a significant role in determining whether revascularization is appropriate to enhance quality of life (i.e., limiting angina while undergoing OMT is a more compelling indication than episodic, exertional angina during minimal medical therapy).

3. The patient's treatment preferences and sociodemographic/clinical circumstances should always be a consideration in guiding which treatment strategy should be used.
4. In certain clinical circumstances it may be difficult to reliably ascertain whether anginal symptoms or anginal equivalents such as exertional dyspnea or fatigue are a direct manifestation of underlying CAD, especially in patients with significant obesity, those who are sedentary, or those who may have coexisting chronic obstructive pulmonary disease. In such settings, symptoms that are either atypical for or nondiagnostic of obstructive CAD may not necessarily improve with revascularization, even when such symptoms coexist with physiologically significant CAD.
5. The decision to proceed with myocardial revascularization in a patient with SIHD should entail a thoughtful, transparent discussion of all potential treatment options, with full disclosure of the anticipated benefits and potential risks associated with PCI or CABG relative to guideline-directed medical therapy. In an elective setting in which urgent/emergency PCI is not being contemplated to reduce the possibility of death or MI, use of a "heart team," as cited earlier, is both prudent and clinically appropriate. Although it is often very common to undertake ad hoc PCI once the patient's coronary anatomy is defined in the catheterization laboratory, it is frequently difficult to have the type of discussion that would involve a complete review of the potential risks and benefits of all treatment options by the "heart team" in this setting. It has been suggested that a "time out," or hitting the "therapeutic pause button," might facilitate a more thorough understanding of what is best for a particular patient, particularly one with extensive multivessel CAD. In summary, treatment decisions must be individualized according to the specific clinical features and personal preferences of a given patient (often in collaboration with family members and the patient's referring physician), along with informed discussion about the potential risks and benefits of all three therapeutic options.

Percutaneous Coronary Intervention (see Chapter 55)

PCI, which includes percutaneous transluminal coronary angioplasty (PTCA), stenting, and related techniques, has continued to evolve significantly over the past three decades. PTCA has been replaced since the advent of bare metal stents (BMSs) in the mid-1990s, followed by the introduction of drug-eluting stents (DESs) in 2003 and subsequent evolutions in design to include thinner struts and improved drug-eluting platforms and delivery systems to minimize both restenosis and acute, subacute, and late/very late stent thrombosis. Moreover, the practice of interventional cardiology has evolved significantly with the advent of improved adjunctive pharmacotherapy and advances in technology other than stenting, such as distal protection devices and devices directed at specific technical issues (e.g., thrombectomy and atherectomy catheters).¹⁶¹ PCI is an important treatment modality in patients with SIHD, particularly in those with chronic angina who remain symptomatic despite optimal guideline-directed medical therapy. The technical aspects, early outcomes, and long-term outcomes of PCI are discussed in [Chapter 55](#). This section focuses on comparisons with medical therapy and when to select PCI as part of a therapeutic strategy.

Among the many desirable features of PCI is the fact that it can be performed during the same clinical encounter as diagnostic angiography. Stable patients can often be discharged on the same or next day, and clinical recovery is usually complete within a week or less. In many instances, relief of symptoms may be immediate and dramatic. Such attributes can motivate some patients to elect to undergo PCI even when medical therapy alone may lower overall risk with equivalent long-term outcomes.

Early Outcome (See Chapter 55). Continued improvement in the technical aspects of PCI (predominantly coronary stenting), as well as increasing operator experience, has had a favorable impact on the rate of primary success and the rate of reductions in complications. The ACC National Cardiovascular Data Registry (ACC-NCDR) has reported

an angiographic success rate of 96% and a procedural success rate (angiographic success without death, heart attack, or emergency revascularization) of 93% in patients undergoing PCI. The incidence of death before hospital discharge is less than 1%, and emergency CABG is required in 0.3% of cases. The ACC-NCDR has also reported a periprocedural MI rate of 1%. Although studies using routine assessment of cardiac biomarkers have reported higher rates, the significance of increases in these periprocedural biomarkers is debated.¹⁶² Finally, the rate of restenosis with DESs is reported to be less than 10% with a corresponding approximately 20% decrease in the need for repeat revascularization procedures relative to the era of BMSs.¹⁶³ Outcomes in specific challenging subgroups of patients, such as those with chronic total occlusions or left main coronary stenosis, are discussed in [Chapter 55](#).

Long-Term Outcome

Stenting versus Angioplasty (see [Chapter 55](#)). Meta-analyses of trials of routine stenting versus balloon angioplasty have not demonstrated differences in the incidence of death, MI, or emergency CABG. In an analysis of 23 trials involving 10,347 patients, BMSs produced rates of mortality similar to those of balloon angioplasty (odds ratio, 0.92; $P = 0.60$), as well as similar rates of a combined endpoint of death or MI (odds ratio, 0.86; $P = 0.2$).⁴⁰ However, stenting led to significantly fewer major adverse cardiac events (odds ratio, 0.59; $P < 0.001$) as a result of reduced repeat revascularization. In another analysis of 27 trials totaling 9918 patients, stenting produced similar mortality (odds ratio, 0.65; $P = \text{not significant [NS]}$) and death/MI (odds ratio, 0.90; $P = \text{NS}$) as balloon angioplasty, but with less frequent restenosis (odds ratio, 0.52; CI, 0.37 to 0.69).⁴⁰

Restenosis and Late Stent Thrombosis. See [Chapter 55](#).

Comparisons between Percutaneous Coronary Intervention and Medical Therapy

Studies comparing balloon angioplasty with medical therapy in the pretest era are of uncertain clinical relevance today because both PCI and medical treatments have undergone profound changes over the past one to two decades. Moreover, randomized clinical trials comparing PCI with medical therapy are few in number and have involved fewer than 9000 patients (in total). Most have enrolled patients with predominantly single-vessel disease and were completed before the routine use of coronary stenting and enhanced adjunctive pharmacotherapy. In aggregate, the results of these 16 trials have supported better control of angina, improved exercise capacity, and improved quality of life in patients treated with angioplasty versus medical therapy ([Fig. 54-11](#)).¹⁶⁴ However, a meta-analysis of eight trials of stenting versus medical therapy indicated that the initial improvement in relief of angina with PCI over medical therapy is not sustained in the era of contemporary medical therapy ([Fig. 54-11](#)).¹⁶⁵ In addition, no randomized trial or meta-analysis has demonstrated a reduction in death or MI with PCI versus medical therapy for patients with SIHD.

Between 1999 and 2004, the COURAGE (Clinical Outcomes Utilization Revascularization and Aggressive Drug Evaluation) trial research group randomly assigned 2287 patients with objective evidence of ischemia and proximal angiographic CAD ($\geq 70\%$ visual stenosis) to OMT with or without PCI.¹⁶⁶ The aim and design of the COURAGE trial were to test a strategy of routine, anatomically driven PCI plus OMT versus a strategy of selective, ischemia-driven PCI, if needed, for failure of initial OMT. Follow-up of 2.5 to 7 years (median, 4.6 years) demonstrated that death or MI occurred with similar frequency in both arms (HR for PCI + OMT versus OMT, 1.05; 95% CI, 0.87 to 1.27; $P = 0.62$) ([Fig. 54-12](#)). A comparison of the PCI-plus-OMT and the OMT groups found no differences in hospitalization for ACS (HR, 1.07; 95% CI, 0.84 to 1.37; $P = 0.56$) or MI (HR, 1.13; 95% CI, 0.89 to 1.43; $P = 0.33$). Thus the main study findings indicated that as an initial management strategy in patients with SIHD, PCI did not reduce death, MI, or other major cardiovascular events when added to OMT. Patients initially treated with PCI had less angina at 1 and 3 years, but not at 5 years, than did patients initially treated without PCI. As expected, in patients who received OMT initially, subsequent PCI was performed more frequently than in those initially treated with PCI, although only 16.5% of OMT patients required revascularization during the first year of follow-up whereas the remaining 16.1% of

FIGURE 54-11 **A**, Relative risk for recurrent cardiac events with PTCA versus medical therapy from a meta-analysis of six randomized trials ($N = 1904$). When compared with medical therapy, angioplasty reduced the relative risk for recurrent angina by 30%. Randomized trials have not included sufficient numbers of patients for informative estimates of the effect of angioplasty on MI, death, or subsequent revascularization; however, trends in the data available do not favor angioplasty. These trials do not reflect the widespread use of coronary stenting. *Test for heterogeneity, $P < 0.0001$. **B**, Relative risk for recurrent cardiac events with PCI plus stenting versus medical therapy from a meta-analysis of eight randomized trials ($N = 7229$). Three trials enrolled stable patients after MI, whereas five studies enrolled patients with stable angina and/or ischemia on stress testing. Coronary stenting for SIHD showed no significant benefit over initial medical therapy for prevention of recurrent angina, MI, death, or unplanned revascularization over a median follow-up of 4.3 years. (**A**, From Bucher HC, Hengstler P, Schindler C, et al: Percutaneous transluminal coronary angioplasty versus medical therapy for treatment of non-acute coronary heart disease: A meta-analysis of randomised controlled trials. *BMJ* 321:73, 2000; **B**, data from Stergiopoulos K, Brown DL: Initial coronary stent implantation with medical therapy vs medical therapy alone for stable coronary artery disease: A meta-analysis of randomized controlled trials. *Arch Intern Med* 172:213, 2012.)

patients crossed over to revascularization between years 1 and 7. It is important to recognize that patients in the COURAGE study were highly symptomatic at baseline and had appreciable clinical comorbidity, a high prevalence of objective evidence of myocardial ischemia, and extensive angiographic CAD and thus fall into the population in which a clinical benefit of PCI was expected.¹⁶⁶ Subgroup analyses of the COURAGE trial revealed consistency among clinically relevant special populations: no difference between PCI plus OMT versus OMT in patients with multivessel CAD, low LV ejection fraction, CCS class II or III angina, or diabetes ([Fig. 54-12](#)).¹⁶⁶

Fractional Flow Reserve Strategy

An FFR-guided PCI strategy plus the best available medical therapy was also compared with the best available medical therapy alone in the FAME 2 trial.⁵⁵ In this trial, patients who had lesions with an FFR of 0.8 or less in one or more visually stenotic coronary arteries ($\geq 50\%$ stenosis) were randomly assigned to medical therapy alone or PCI plus medical therapy. The plan was to enroll 1632 patients in the study with a projected minimum 2-year follow-up period; however, the trial was terminated prematurely after enrollment of 888 patients with a mean follow-up of 7 months at the recommendation of the data monitoring committee because of a highly significant reduction in the composite primary endpoint of death, MI, or urgent revascularization. The final analysis revealed a 68% relative risk reduction in the primary endpoint from 12.7% in the medical therapy group to 4.3% in the PCI group (HR, 0.32; 95% CI, 0.19 to 0.53; $P < 0.001$). Notably, the difference was driven solely by a lower rate of urgent revascularization in the PCI group than in the medical therapy group

FIGURE 54-12 Outcome in 2287 patients with objective evidence of MI and significant CAD enrolled in the COURAGE trial and randomly assigned to PCI and OMT or to OMT alone (Medical therapy). **A**, No difference in the primary endpoint of death from any cause or MI was observed between the two treatment groups. **B**, The finding of no difference between the two treatment groups was consistent across multiple subgroups, including patients with multivessel disease, diabetes, severe angina, and previous revascularization. *Interaction p-value. (From Boden WE, O'Rourke RA, Teo KK, et al: Optimal medical therapy with or without PCI for stable coronary disease. *N Engl J Med* 356:1503, 2007.)

(1.6% versus 11.1%; HR, 0.13; 95% CI, 0.06 to 0.30; $P < 0.001$), with no significant difference in death or MI (Fig. 54-13).⁵⁵ As a limitation of this trial, it is possible that in a nonblinded trial, investigators may have had a lower threshold for recommending revascularization for a patient in the medical therapy group who had recurrent angina rather than attempting to continue managing the symptoms with titration of medical therapy, particularly because the definition of unstable angina requiring urgent revascularization did not mandate objective evidence of myocardial ischemia or biomarker positivity, and this accounted for 52% of patients who underwent early revascularization.¹⁶⁷

Findings from both the COURAGE and FAME 2 studies show that PCI reduces ischemic symptoms and the need for future revascularization. Neither the FAME 2 trial (with a mean 7 months of follow-up) nor the COURAGE trial (with a mean 55 months of follow-up) showed a reduction in the rate of death or MI with PCI versus guideline-directed medical therapy. The findings support current guidelines for the selective use of FFR to guide PCI decision making for borderline visual lesions ($\approx 50\%$ to 70% stenosis).⁴⁰ However, there does not appear to be sufficient evidence to support more routine use of FFR for all angiographically significant stenosis; it adds considerable time, cost, and complexity to each PCI.¹⁶⁷

Two substudies from the COURAGE trial provided insight into the complex relationship between noninvasive assessment of ischemia and the potential benefits of revascularization. An earlier substudy of 314 patients who underwent serial baseline and 1-year follow-up stress MPI demonstrated that when compared with the patients who received OMT alone ($n = 155$), patients randomly assigned to PCI plus OMT ($n = 159$) had a greater reduction in high-grade ischemia

(i.e., the between-group difference in mean total person defect during follow-up versus baseline) as assessed by a nuclear core laboratory. However, this substudy was undertaken in only 14% of the overall trial population. Even though a small subset of patients with moderate to severe ischemia ($n = 105$) did demonstrate better suppression of ischemia with PCI, these findings were observed in only 20% of the patients in the nuclear substudy group.¹⁶⁸ Overall, this substudy was too underpowered to establish whether clinical events in such PCI-treated patients with myocardial ischemia were significantly lower than in patients treated medically. By contrast, a more recent, second nuclear substudy from the COURAGE trial was undertaken in 1381 randomly assigned patients (OMT alone = 699 patients; PCI + OMT = 682 patients) who underwent stress myocardial perfusion SPECT at baseline only (with or without a repeated follow-up scan), with the results being interpreted locally by the on-site investigators. At baseline, moderate to severe ischemia was present in one third of patients ($n = 468$), and the incidence was comparable in both treatment groups ($P = 0.36$). The primary endpoint (death or MI) was similar in the two treatment groups for the subsets with either no to mild ischemia (18% and 19%, respectively, $P = 0.92$) or moderate to severe ischemia (19% and 22%, respectively, $P = 0.53$, interaction P value = 0.65) (Fig. 54-14). Moreover, there was no gradient increase in events for the overall cohort based on the extent of ischemia. The discordance of these two substudies supports equipoise regarding whether the extent and severity of myocardial ischemia are favorably affected by PCI,¹⁶⁹ and the premise that severe ischemia may identify an important subset of patients with SIHD who may derive clinical benefit from PCI remains unproven.

Therefore to date, meta-analyses of randomized trials of PCI versus medical therapy for SIHD have demonstrated that mortality, MI, the severity and extent of ischemia, and long-term angina do not differ between these two strategies.¹⁷⁰ However, the question of whether PCI can reduce the risk for cardiovascular death or MI in selected patients at higher risk for ischemia remains under investigation. ISCHEMIA (International Study of Comparative Health Effectiveness with Medical and Invasive Approaches; ClinicalTrials.gov number NCT01471522), funded by the National Heart, Lung and Blood Institute (NHLBI), is presently under way and is designed to evaluate the long-term superiority of revascularization plus guideline-directed medical therapy versus guideline-directed medical therapy alone with respect to cardiovascular death or MI in patients with SIHD and documented moderate to severe myocardial ischemia.

In summary, based on the best available data from randomized trials, it appears reasonable to pursue a strategy of initial medical therapy for most patients with SIHD and CCS class I or II symptoms and to reserve revascularization for those with persistent and/or more severe symptoms despite guideline-directed medical therapy or those with high-risk criteria on noninvasive testing, such as inducible ischemia involving a moderate or large territory of myocardium.¹²⁰

FIGURE 54-13 Outcome of death, MI, or urgent revascularization in 888 patients with stable CAD for whom PCI was being considered. The patients underwent assessment of all stenoses by FFR and were randomly assigned to FFR-guided PCI plus best available medical therapy or the best available medical therapy alone. **A**, Enrollment was halted prematurely because of a significant reduction in the primary endpoint in patients treated with an FFR-guided revascularization strategy: 4.3% in the PCI group and 12.7% in the medical therapy group (HR with PCI, 0.32; 95% CI, 0.19 to 0.53; $P < 0.001$). **B**, However, this effect on the primary endpoint was driven entirely by a reduction in unplanned revascularization (Revasc) rather than by death or MI. (Modified from De Bruyne B, Piljls NH, Kalesan B et al: Fractional flow reserve-guided PCI versus medical therapy in stable coronary disease. *N Engl J Med* 367:998, 2012.)

Patient Selection for Percutaneous Coronary Intervention

In addition to general considerations regarding the indications and approach to revascularization (see [Approach to Decision Making Regarding Revascularization](#)), additional factors that need to be weighed in selecting patients for PCI include the following:

1. The likelihood of successful catheter-based revascularization based on the angiographic characteristics of the lesion
2. The risk and potential consequences of acute failure of PCI, which are a function, in part, of the coronary artery anatomy (multivessel and/or diffuse disease), the percentage of viable myocardium at risk, the presence of heart failure, and underlying LV function
3. The likelihood of restenosis, which has been associated with clinical (e.g., diabetes, previous restenosis) and angiographic factors (small vessel diameter, long lesion length, total occlusion, and saphenous vein graft disease) (see [Chapter 55](#))
4. The need for complete revascularization based on the extent of CAD and the volume of myocardium and the severity of ischemia in the distribution of the artery or arteries amenable to PCI

FIGURE 54-14 Patients with SIHD were randomly assigned to OMT alone or PCI plus OMT. In a subgroup analysis of 1381 patients who underwent stress MPI at baseline, the relationship between ischemia and subsequent outcome with the randomized interventions was examined. Cumulative rates of the primary endpoint all-cause death or MI in patients with no to mild (A) and with moderate to severe (B) baseline ischemia revealed no benefit of PCI in patients with no or mild ischemia or those with moderate to severe ischemia. (From Shaw LJ, Weintraub WS, Maron DJ, et al: Baseline stress myocardial perfusion imaging results and outcomes in patients with stable ischemic heart disease randomized to optimal medical therapy with or without percutaneous coronary intervention. *Am Heart J* 164:247, 2012).

Percutaneous Coronary Intervention in Specific Subgroups of Patients with Stable Ischemic Heart Disease

Diabetes Mellitus. Patients with diabetes are at substantially higher risk for complications after PCI (see Chapter 61). Possible explanations for the higher rate of adverse outcomes include an altered vascular biologic response to balloon injury in patients with diabetes and rapid progression of disease in nondilated segments. The diabetic atherosclerotic milieu is characterized by a procoagulant state, decreased fibrinolytic activity, increased proliferation, and inflammation. Restenosis is more frequent in patients with diabetes, as is disease progression. For this reason, CABG, which bypasses most of the vessel instead of a specific lesion, may offer a better intermediate- to long-term outcome. The optimal strategy for revascularization in patients with diabetes is discussed later in this chapter. A strategy of initial OMT appears to be reasonable for most patients with diabetes and SIHD.¹⁷¹

Left Ventricular Dysfunction. Despite advances in interventional cardiology, LV dysfunction remains independently associated with higher in-hospital and long-term mortality after PCI. Specifically, in patients with stable CAD and estimated ejection fractions of 0.40 or less, 0.41 to 0.49, and 0.50 or higher in the NHLBI Dynamic Registry, mortality at 1 year after PCI was 11.0%, 4.5%, and 1.9%, respectively. Contemporary trials of PCI versus medical therapy have included too few patients with impaired LV function to guide therapeutic decision making in this important subset of patients.

Women and Older Patients. Specific issues related to PCI in women and older adults are discussed in Chapters 76 and 77. A post hoc study from the COURAGE trial showed that 40% of the patients who were 65 years or older had a twofold higher rate of death or MI than did younger patients, although no age-related differences in clinical outcomes were noted in patients randomly assigned to PCI or OMT. Of note, despite the potential increased risk for complications in older patients undergoing PCI, no such increased rate of comorbid conditions (e.g., local vascular complications, worsening renal function, bleeding) was noted.¹⁷²

Renal Dysfunction. Patients with impaired renal function (generally those with an eGFR <60 mL/min), particularly those with diabetes, may be at increased risk for worsening azotemia (see Chapter 88), and this is often an important consideration in the physician's decision of whether to proceed with coronary angiography and PCI in such patients. A post hoc analysis from the COURAGE trial evaluated

clinical outcomes and complications in patients with an eGFR lower than 60 mL/min. This analysis, as expected, showed that patients with decreased renal function had a significantly higher long-term rate of cardiovascular events than did those whose eGFR was 60 mL/min or higher, but there was neither evidence of clinical benefit nor harm in patients with reduced renal function who underwent PCI versus OMT, thus suggesting that treatment decisions in such patients should be appropriately individualized on the basis of anticipated benefits and risks.¹⁷³

Previous Coronary Bypass Grafting. CABG and PCI are often considered competitive procedures, but it is more appropriate to view them as complementary. An increasing number of patients who have treated with CABG and later have recurrent ischemia undergo revascularization with PCI. The technical aspects and procedural outcomes of PCI in patients with venous bypass grafts are discussed in Chapter 55.

Coronary Artery Bypass Grafting

In 1964, Garrett, Dennis, and DeBakey first used CABG as a “bailout” procedure. Widespread use of the technique by Favoloro and Johnson and their respective collaborators followed in the late 1960s. Use of an internal mammary artery (IMA) graft was pioneered by Kolessov in 1967 and by Green and colleagues in 1970. Since then CABG has evolved progressively over the past four decades and today remains an important treatment modality for many patients with SIHD. Most bypass operations continue to be performed through a median sternotomy with the use of either cardiopulmonary bypass (CPB) and cardioplegic myocardial arrest or without bypass on a beating heart. Less invasive approaches have become increasingly commonplace in selected patients who may be appropriate candidates for more limited coronary revascularization, including anterior and lateral thoracotomies, partial sternotomies, and epigastric incisions. The technical goal of bypass surgery is to achieve, whenever possible, complete revascularization by grafting all coronary arteries of sufficient caliber that have physiologically significant proximal stenoses. CABG has been documented to prolong survival, relieve angina, and improve quality of life in specific subgroups of patients with CAD.¹⁷⁴⁻¹⁷⁶

The annual number of CABG operations in the United States rose steadily over the first three decades, with a peak in the late 1990s. Since then, however, rates of CABG have steadily declined, which is probably related to sustained growth of the use of PCI, particularly in patients with multivessel CAD.³ CABG provides excellent short- and intermediate-term results in the management of SIHD; its long-term results are affected by failure of venous grafts. Long-term data with totally arterial surgical revascularization (i.e., using bilateral IMA grafts) are few.

Minimally Invasive Coronary Artery Bypass Surgery

Less invasive or minimally invasive approaches may be divided into four major categories based on the approach and use of CPB. Port-access CABG is performed through limited incisions with femoral-femoral CPB and cardioplegic arrest. Port-access technology has also now enabled totally endoscopic robotically assisted CABG (TECAB) surgery to be performed on the arrested heart.¹⁷⁷ Off-pump CABG (OPCAB) is performed by using a standard median sternotomy, with generally small skin incisions, and stabilization devices to reduce motion of the target vessels while anastomoses are performed without CPB.¹⁷⁸ Finally, minimally invasive direct coronary artery bypass (MIDCAB) is performed through a left anterior thoracotomy without CPB.¹⁷⁹ Thus off-pump approaches to CABG include both OPCAB and MIDCAB techniques (Fig. 54-e3).

Potential advantages of the minimally invasive approaches include reduced postoperative patient discomfort, minimized risk for wound infection, and shorter recovery times.¹⁷⁸ Avoidance of CPB may mitigate the risk for bleeding, systemic thromboembolism, renal insufficiency, myocardial stunning, and stroke and the damaging neurologic effects of CABG, which may result in cognitive impairment, particularly in older adults and those with heavily calcified aortas. Amelioration of the systemic inflammatory response that occurs after the CABG-plus-CPB technique is viewed as an additional advantage that may affect these clinical outcomes. The learning curve of minimally invasive CABG has led to some reports of early graft failure. It should be emphasized that with conventional surgical technique, the early patency rates of an IMA graft are excellent (98.7% in one large series).

Short-term clinical and angiographic outcomes have suggested that the less invasive techniques can be used to achieve results comparable to those of traditional CABG. However, in 2009 a comparative trial of OPCAB versus CABG plus CPB in 2203 patients revealed no difference in death or complications at 30 days (7.0% versus 5.6%, respectively, $P = 0.19$) but a significantly worse 1-year composite outcome of all-cause mortality, nonfatal MI, and need for repeat revascularization in off-pump versus on-pump procedures (9.9% versus 7.4%, respectively, $P = 0.04$).¹⁸⁰ Additionally, in patients undergoing follow-up angiography, the graft patency rate was significantly lower in OPCAB recipients, with no treatment-based differences in neuropsychological outcomes or short-term resource use. Thirty-day outcomes of off-pump versus on-pump CABG in the CORONARY (CABG Off or On Pump Revascularization Study) trial had similar results in 4752 patients randomly assigned to OPCAB versus traditional CABG. Although the duration of the operation and subsequent mechanical ventilation were both reduced, as was the incidence of postoperative bleeding and acute kidney injury, the primary composite outcome of death, MI, stroke, or renal failure requiring dialysis did not differ between groups (9.8% versus 10.3%; HR, 0.95; 95% CI, 0.79 to 1.14; $P = 0.59$), but the need for early revascularization was increased (Fig. 54-15).¹⁸¹ In addition, data on long-term outcomes after OPCAB are conflicting,¹⁸² with concern remaining that poorer graft patency and incomplete revascularization may contribute to a hazard associated with OPCAB.^{183,184} Therefore although generally consistent findings across randomized and observational data sets support reductions in blood loss and/or transfusion requirements, fewer wound infections, less postoperative atrial fibrillation, lower indices of myocardial injury, shorter duration of mechanical ventilation, and earlier hospital discharge with OPCAB, additional data on long-term survival and neurocognitive function are needed to assist

FIGURE 54-15 Outcome of death, nonfatal stroke, MI, or new renal failure requiring dialysis at 30 days after random assignment in 4752 patients undergoing CABG and randomly assigned to surgery with CPB (on-pump) or without CPB (off-pump). No significant difference was found in the rate of the primary endpoint between off-pump and on-pump CABG (9.8% versus 10.3%; HR, 0.95; 95% CI, 0.79 to 1.14; $P = 0.59$) or in any individual elements of the composite endpoint. Transfusions of blood products, reoperation for bleeding, and acute kidney injury were reduced in the off-pump group. Early repeated revascularizations were, however, increased in the off-pump group. * $P < 0.05$. (Modified from Lamy A, Devereaux PJ, Prabhakaran D, et al: Off-pump or on-pump coronary-artery bypass grafting at 30 days. *N Engl J Med* 366:1489, 2012.)

in assessing the comparative effectiveness of these two approaches on clinical outcomes.¹⁷⁸

Novel approaches to coronary revascularization may also include CABG with PCI by combining a minimally invasive surgical CABG procedure on the LAD coronary artery (i.e., a left IMA implant to the proximal LAD coronary artery using OPCAB) with PCI on the remaining vessels.¹⁸⁵ Additional experience with these so-called hybrid revascularization procedures is needed to further clarify appropriate selection criteria and to determine whether this strategy offers important advantages over multivessel CABG alone.

Arterial and Venous Conduits. The current standard for bypass grafting advocates routine use of the left IMA for grafting the LAD coronary artery and supplemental saphenous vein grafts to other vessels. Although the benefits of a single IMA graft over a saphenous vein graft alone are not in dispute, the superiority of bilateral IMA grafts over a single IMA graft and one saphenous vein graft is less well accepted. Initial enthusiasm for the use of bilateral IMA grafts was tempered by a higher rate of postoperative complications, including bleeding, wound infection, and prolonged ventilatory support. Wound infection, most notably deep sternal wound infection, has been of particular concern but remains modest in frequency (<3%), except in patients who are obese or have diabetes or those who require prolonged ventilatory support. Subsequent series have shown that bilateral versus single IMA grafting is associated with lower rates of recurrent angina pectoris, reoperation, and MI and improved survival in nonrandomized studies, and in some series the risk for wound infection does not differ substantially from that with single IMA grafts. In a randomized trial of 3102 patients undergoing CABG, the use of bilateral IMA grafts conferred similar outcomes at 30 days and 1 year as the use of a single IMA graft with the exception of a small increase in the need for sternal wound reconstruction.¹⁸⁶ Long-term (10 year) follow-up in this trial remains ongoing. The increased technical demands and longer operative times of bilateral IMA grafting have also been a barrier to more widespread adoption but may be overcome if evidence supporting a survival advantage continues to accumulate.^{187,188}

Patency of Venous and Arterial Grafts. Early occlusion (before hospital discharge) occurs in 8% to 12% of venous grafts, and by 1 year, 15% to 30% of vein grafts have become occluded. After the first year the annual occlusion rate is 2% and rises to approximately 4% annually between years 6 and 10. Patency rates with IMA grafts are superior.

Distal Vasculature. The state of the distal coronary vasculature is important for the fate of bypass grafts. Late patency of grafts is related to coronary arterial runoff as determined by the diameter of

the coronary artery into which the graft is inserted, the size of the distal vascular bed, and the severity of coronary atherosclerosis distal to the site of insertion of the graft. The highest graft patency rates are found when the lumina of vessels distal to the graft insertion are larger than 1.5 mm in diameter, perfuse a large vascular bed, and are free of atheroma obstructing more than 25% of the vessel lumen. For saphenous veins, optimal patency rates are achieved with a lumen of 2.0 mm or larger.

Progression of Disease in Native Arteries. The rate of disease progression appears to be highest in arterial segments already showing evidence of disease, and it is between three and six times higher in grafted native coronary arteries than in nongrafted native vessels. These data have suggested that bypassing an artery with minimal disease, even if initially successful, may ultimately be harmful to patients, who incur both a risk for graft closure and an increased risk for accelerated obstruction of native vessels. Lesions in the native vessel that are long (>10 mm) and greater than 70% in diameter are at increased risk for progressing to total occlusion.

Effects of Therapy on Vein Graft Occlusion and Native Vessel Progression. Measures aimed at enhancing long-term patency are generally directed at delaying the overall process of atherosclerosis, and thus they may have several additional benefits.¹⁸⁹ Secondary preventive therapy, in particular, aspirin and lipid-lowering treatment, is important in reducing the risk for failure of venous grafts. Chronic anticoagulant therapy has *not* been convincingly shown to alter outcomes. Other novel approaches, such as pretreatment of venous grafts to increase resistance to atherothrombosis, have not been definitively evaluated.

Antiplatelet Therapy. Several trials have demonstrated the efficacy of aspirin therapy when started 1, 7, or 24 hours preoperatively, but the benefit is lost when aspirin is started more than 48 hours postoperatively. Aspirin, 75 to 325 mg daily, should be continued indefinitely. The addition of dipyridamole or warfarin in conventional doses has not been definitively shown to provide added benefit. Although the effects of clopidogrel on graft patency have not been studied specifically, it is likely to be at least as effective as aspirin and is recommended in those who have an allergy to aspirin or who have recently experienced an ACS.

Lipid-Lowering Therapy. Three randomized trials of lipid-lowering therapy have shown a favorable impact on the development of graft disease. The rationale for lowering the LDL cholesterol concentration to less than 100 mg/dL in patients with CAD was extended to postoperative patients in the Post-Coronary Artery Bypass Graft Trial.

Patient Selection

Indications for CABG are centered on the need for improvement in the quality and/or duration of life.^{175,176} The decision to perform revascularization with PCI or CABG is determined largely from the coronary anatomy, LV function, other medical comorbid conditions that may affect the patient's risk associated with either revascularization procedure, and patient preference (see [Approach to Decision Making Regarding Revascularization and Choosing between Percutaneous Coronary Intervention, Coronary Artery Bypass Surgery, and Medical Therapy](#)).¹⁵⁶ CABG is indicated, regardless of symptoms, for patients with CAD in whom survival is likely to be prolonged and for those with multivessel CAD in whom noninvasive testing suggests high risk (see Table 57-11).

Patients with more extensive and severe CAD have an increasing magnitude of benefit from CABG over medical therapy (Figs. 54-16 and e54-4; see also Table 57-12). Patients with left main and/or three-vessel CAD and, in particular, those with LV systolic dysfunction should be considered candidates for CABG to prolong life, whereas similar data support the benefits of CABG in diabetic patients with multivessel CAD if revascularization is needed. Other factors that must always be considered in the decision are general health and non-coronary-related comorbid conditions that influence both the risks associated with surgery and the likelihood of durable functional benefit.

Surgical Outcomes and Long-term Results

The patient population undergoing CABG has been changing over time, particularly with the wider use of PCI. When compared with the 1970s, patients undergoing CABG today are older, include a higher percentage of women, and are sicker in that a greater proportion have unstable angina, triple-vessel CAD, previous coronary revascularization with either CABG or PCI, LV dysfunction, and comorbid conditions, including hypertension, diabetes, and peripheral vascular disease. Despite the increasing risk profile of this population, outcomes with CABG have generally remained stable or have improved.

Operative Mortality

Risk factors for death following CABG may be separated into five categories: (1) preoperative factors related to CAD, including recent acute MI, hemodynamic instability, LV dysfunction, extensive CAD, the presence of left main CAD, and severe or unstable angina;

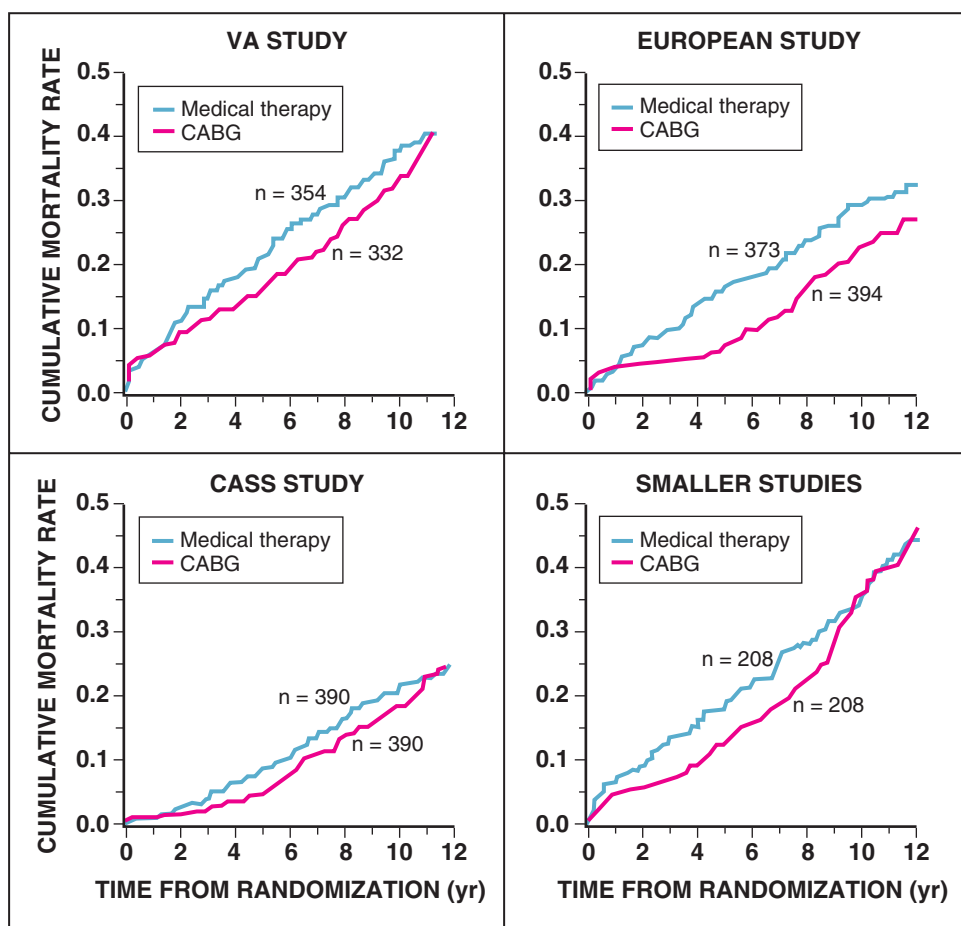

FIGURE 54-16 Survival curves of three large randomized trials of medical therapy versus CABG and four smaller studies combined. (From Eagle KA, Guyton RA, Davidoff R, et al: ACC/AHA guidelines for coronary artery bypass graft surgery: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee to Revise the 1991 Guidelines for Coronary Artery Bypass Graft Surgery]. *J Am Coll Cardiol* 34:1262, 1999.)

FIGURE e54-4 A, Adjusted hazard (mortality) ratios comparing CABG surgery and medical therapy for nine coronary anatomy severity groups (GR) according to the number of vessels diseased (VD), the presence or absence of a 95% proximal stenosis, and involvement of the LAD coronary artery. **B**, Adjusted hazard (mortality) ratios comparing CABG surgery and PTCA for nine coronary anatomy groups according to the number of vessels diseased, the presence or absence of a 95% proximal stenosis, and LAD involvement. In patients with the least severe categories of disease, 5-year survival appears to be better with PTCA (single-vessel disease without proximal stenosis and without LAD involvement), whereas for patients with triple-vessel disease and higher grade, more complex double-vessel disease, a survival benefit is noted with surgery. For other subsets of patients with double-vessel disease, no difference in survival was seen in those treated with CABG surgery or PTCA, and many of these patients are probably similar to those included in the randomized trials. (From Jones RH, Kesler K, Phillips HR III, et al: Long-term survival benefits of coronary artery bypass grafting and percutaneous transluminal angioplasty in patients with coronary artery disease. *J Thorac Cardiovasc Surg* 111:1013, 1996.)

(2) preoperative factors related to the aggressiveness of the arteriosclerotic process, as reflected by associated carotid or peripheral vascular disease; (3) preoperative biologic factors (older age at surgery, diabetes mellitus, other comorbid conditions, including pulmonary and renal disease, and perhaps female sex); (4) intraoperative factors (intraoperative ischemic damage and failure to use IMA grafts); and (5) environmental or institutional factors, including the specific surgeon and treatment protocols used. Of these factors, several variables have consistently emerged as the most potent predictors of mortality after CABG: (1) age, (2) urgency of surgery, (3) previous cardiac surgery, (4) LV function, (5) percent age stenosis of the left main coronary artery, and (6) the number of epicardial vessels with significant disease.

In-hospital mortality after isolated CABG has continued to decline over the past several decades. Despite a shift toward higher-risk demographics, increasing age, and clinical comorbidity, early mortality continued to decline in the 1990s. The cumulative mortality in almost 1.5 million CABG-only operations recorded in the Society of Thoracic Surgeons (STS) data base declined from 3.05% between 1997 and 1999 to approximately 2% in 2008 and remained less than 2% in 2013.¹⁹⁰ Operative mortality rates for isolated CABG now range from approximately 1.5% to 2.0%. Several models have been developed and refined with the objective of predicting perioperative mortality. Application of such models has demonstrated even greater declines in CABG-related mortality over the past decade when adjusted for changes in clinical risk profile.

Perioperative Complications. Perioperative morbidity has increased because of a larger fraction of higher-risk patients. Major morbidity (e.g., death, stroke, renal failure, reoperation, prolonged ventilation, sternal infection) occurred in 13.4% through 30 days in the 503,478 CABG-only operations recorded in the STS data base between 1997 and 1999.¹⁹⁰

Myocardial Infarction. Perioperative MI, particularly if associated with hemodynamic or arrhythmic complications or with preexisting LV dysfunction, has a major adverse effect on early and late prognosis. The reported incidence varies widely (0% to >10%), in large part because of heterogeneous diagnostic criteria, with an average of 3.9% (median, 2.9%). The diagnostic criteria for MI in the setting of CABG have been revised and are now based on elevation of cardiac troponin or a myocardial creatine kinase-MB (CK-MB) isoenzyme level more than 10 times the upper limit of normal in association with objective evidence of myocardial dysfunction.¹⁹¹ Data from a prospectively performed study involving routine monitoring of biomarkers of necrosis postoperatively has shown CK-MB and cardiac troponin to be independently associated with mortality. Predictors of perioperative MI in CASS (Coronary Artery Surgery Study) were female sex, severe perioperative angina pectoris, severe stenosis of the left main coronary artery, and triple-vessel CAD.

Cerebrovascular Complications. Neurologic abnormalities following cardiac surgery are dreaded complications and are associated with higher long-term mortality.¹⁹² Postulated mechanisms include emboli from atherosclerosis of the aorta or other large arteries, emboli possibly from the CPB machine circuit and its tubing, and intraoperative hypotension, particularly in patients with preexisting hypertension.¹⁹³ Type I injury is associated with major neurologic deficits, stupor, and coma, and type II injury is characterized by deterioration in intellectual function and memory. The incidence of neurologic abnormalities is variably estimated, depending on how the deficits are defined. Findings of perioperative silent brain injury detected by magnetic resonance imaging techniques are present in 25% to 50% of patients after CABG.¹⁹⁴ The incidence of stroke reported in the Northern New England Cardiovascular Disease Study Group data base between 1992 to 2001 was 1.6% and has been documented to be higher in prospective studies (1.5% to 5%). Studies aimed at careful evaluation of neurologic deficits report more frequent neurologic sequelae; type I deficits have been documented in 6% of patients early after CABG, with short-term cognitive decline occurring in 33% to 83%. A prospective long-term study using sophisticated neurocognitive testing revealed cognitive decline in 53% of patients at the time of hospital discharge, in 36% at 6 weeks, and in 24% at 6 months. In regard to the neurologic sequelae of CPB (including stroke, delirium, and neurocognitive dysfunction), older age, in addition to other comorbid conditions (particularly diabetes), and intraoperative manipulation of the aorta are powerful predictors.¹⁹² In most but not all

studies, atherosclerosis of the proximal aorta has also been a strong predictor of stroke, as has the use of an intra-aortic balloon pump. CABG performed without CPB may be associated with reduced risk for stroke.¹⁸²

Atrial Fibrillation. This arrhythmia is one of the most frequent complications of CABG.¹⁹⁵ It occurs in up to 40% of patients, primarily within 2 to 3 days. In the early postoperative period, rapid ventricular rates and loss of atrial transport may compromise systemic hemodynamics, increase the risk for embolization, and lead to a significant increase in the duration and cost of the hospital stay, and it is associated with a twofold to threefold increase in postoperative stroke. Older age, hypertension, previous atrial fibrillation, and heart failure are associated with a higher risk for the development of atrial fibrillation after cardiac surgery. Previous statin therapy may be accompanied by less frequent postoperative atrial fibrillation.¹⁹⁶

Prophylactic use of beta-blocking agents reduces the frequency of postoperative atrial fibrillation; such drugs should be administered routinely before and after CABG to patients without contraindications. Amiodarone is also effective in prophylaxis against postoperative atrial fibrillation and may be considered in patients at high risk for the development of this dysrhythmia (see Chapter 38).^{197,198} Off-pump techniques may be associated with less frequent postoperative atrial fibrillation. Up to 80% of patients spontaneously revert to sinus rhythm within 24 hours without treatment other than digoxin or other agents used for controlling the ventricular rate. In a randomized trial of patients with postoperative atrial fibrillation that had resolved before discharge, there was no detectable benefit of extended antiarrhythmic therapy beyond a short course of 1 week.¹⁹⁹ Most patients return to sinus rhythm by 6 weeks after surgery.

Renal Dysfunction. The incidence of renal failure requiring dialysis after CABG remains low (0.5% to 1.0%), but it is associated with significantly greater morbidity and mortality (see Chapter 88).²⁰⁰ A decline in renal function, defined as a postoperative serum creatinine level higher than 2.0 mg/dL or an increase of more than 0.7 mg/dL, is more frequent (7% to 8%). Predictors of postoperative renal dysfunction include advanced age, diabetes, preexisting renal dysfunction, and heart failure.²⁰¹ Correspondingly, elevated natriuretic peptide concentrations are associated with a higher risk for perioperative acute kidney injury and add modestly to clinical risk factors.²⁰² Patients with preoperative renal dysfunction and a serum creatinine level higher than 2.5 mg/dL appear to be at increased risk for the need for hemodialysis and may be candidates for alternative approaches to revascularization or prophylactic dialysis. A meta-analysis of randomized trials of *N*-acetylcysteine for preventing the development of renal dysfunction in 1163 patients undergoing cardiac surgery showed no difference in comparison to placebo.²⁰³

Relief of Angina

Trials in which the contemporary practice of using one or more arterial grafts was prevalent have demonstrated similar or superior rates of freedom from angina during short-term and mid-term follow-up. All the major randomized trials have demonstrated greater relief of angina, better exercise performance, and a lower requirement for antianginal medications in surgically treated than in medically treated patients 5 years postoperatively. Independent predictors of recurrence of angina include female sex, obesity, and lack of use of the IMA as a conduit. In patients with triple-vessel CAD undergoing CABG, the completeness of revascularization is a significant determinant of the relief of symptoms at 1 year and over a 5-year period. After 5 years, approximately 75% of surgically treated patients can be predicted to be free of an ischemic event, sudden death, occurrence of MI, or recurrence of angina; approximately 50% remain free for approximately 10 years and around 15% for 15 or more years.

Effects on Survival

Clinical practice has been shaped by three major randomized trials of CABG versus medical therapy in which patients were enrolled between 1972 and 1984: the VA (Veterans Affairs) trial, the European Cardiac Society Study (ECSS), and the NHLBI-supported CASS (Fig. 54-16).¹⁷⁶ The evidence base consists of data from 2649 patients participating in these and several smaller trials and has important limitations with respect to application to current practice because the risk profile of patients referred for surgery, as well as the available surgical and medical interventions, has evolved

substantially since these trials were conducted. In particular, these trials antedated the widespread use of one or two IMAs and the disease-modifying therapies (such as aspirin, statins, and inhibitors of the renin-angiotensin system) that are currently used as guideline-directed medical therapy.

Nevertheless, results of the trials of surgical versus medical therapy have generally been highly consistent, and thus major points guiding clinical practice may still be drawn from a meta-analysis of the results. In each of the trials, a survival benefit of CABG emerged during midterm follow-up (2 to 6 years), an advantage that eroded during long-term follow-up. Considered together, the results of these trials support a 4.1% absolute reduction in long-term mortality (10 years) with CABG ($P = 0.03$). Subgroup analyses have revealed several high-risk criteria that identify patients who are likely to sustain a more substantial survival benefit: (1) left main CAD; (2) single- or double-vessel CAD with proximal LAD disease; (3) LV systolic dysfunction; and (4) a composite evaluation that indicates high risk, including severity of symptoms, high-risk exercise tolerance test, history of previous MI, and the presence of ST depression on the resting ECG.

Taken together, the results of all the trials and registries indicate that the sicker the patient—based on the severity of symptoms or ischemia, age, the number of vessels diseased, and the presence of LV dysfunction—the greater the benefit of surgical over medical therapy on survival (Table 54-12 and Fig. e54-4). CABG prolongs survival in patients with significant left main CAD irrespective of symptoms and in patients with triple-vessel CAD that includes the proximal LAD irrespective of LV function. The preponderance of evidence indicates that surgical therapy prolongs life in patients with triple-vessel and double-vessel CAD with impaired LV function, particularly those with proximal narrowing of one or more coronary arteries and severe angina. However, the largest randomized trial of CABG versus medical therapy limited to patients with an LV ejection fraction of 0.35 or less did not show a significant difference between the two approaches with respect to all-cause mortality (see below).²⁰⁴ Patients with angina or evidence of ischemia at a low or moderate level of exercise, especially those with obstruction of the proximal LAD coronary artery, may benefit from coronary revascularization by PCI or CABG.

Patients with Depressed Left Ventricular Function (See Chapter 49).

Depressed LV function is one of the most powerful predictors of perioperative and late mortality. In the New York State CABG registry, an ejection fraction of 0.25 or less was associated with 6.5% in-hospital mortality as compared with 1.4% in those with an ejection fraction greater than 0.40. As the population ages and the proportion undergoing reoperation increases, the number of patients with preoperative LV dysfunction and clinical heart failure will increase. In the CABG Patch trial confined to patients with an ejection fraction of 0.35 or less, perioperative mortality was 3.5% for patients without clinical signs of heart failure versus 7.7% for those with NYHA Classes I to IV heart failure.

Although the effect of a reduced ejection fraction on operative mortality cannot be eliminated, careful attention to intraoperative metabolic, inotropic, and mechanical support, including preoperative intra-aortic balloon counterpulsation in some patients, may decrease perioperative mortality in comparison to the mortality rates expected from prediction models. In addition to advances in myocardial protection for those undergoing CABG with CPB, off-pump approaches to CABG may also lead to improved outcomes in this high-risk population. Thus in experienced centers, in-hospital mortality for patients with severe LV dysfunction is less than 4% to 5%.²⁰⁵

The powerful effect of the preoperative ejection fraction on late survival emphasizes the fact that currently, the presence of LV dysfunction, in association with viable myocardium, has changed from a relative contraindication to CABG to a potential indication.¹⁷⁶ This shift in focus occurred in concert with the recognition that viable dysfunctional myocardium may improve after coronary revascularization. Indeed, in the largest meta-analysis of randomized trials of CABG versus medical therapy, the most striking survival benefits of CABG, as well as symptomatic and functional improvements, were shown by patients with impaired LV function, in whom the prognosis with medical therapy is poor. This conclusion is also supported by large

FIGURE 54-17 Patients (N = 1212) with CAD amenable to CABG and an ejection fraction of 0.35 or less were randomly assigned to medical therapy alone or medical therapy plus CABG. **A**, There was no significant difference in the rate of death from any cause, which occurred in 41% of the medical therapy group and 36% in the CABG group (HR, 0.86; 95% CI, 0.72 to 1.04; $P = 0.12$). **B**, The secondary combined endpoint of death from any cause or hospitalization for cardiovascular causes was lower in the CABG group (58% versus 68%; HR with CABG, 0.74; 95% CI, 0.64 to 0.85; $P < 0.001$). (Modified from Velazquez E, Lee KL, Deja MA, et al: Coronary-artery bypass surgery in patients with left ventricular dysfunction. *N Engl J Med* 364:1607, 2012.)

contemporary registries.²⁰⁶ However, in the randomized STICH (Surgical Treatment for Ischemic Heart Failure) trial of predominantly on-pump CABG versus medical therapy in 1212 patients with CAD amenable to revascularization and an ejection fraction of 0.35 or less in the absence of left main CAD or severe (class III) angina, the rate of death from any cause at an average of 56 months after randomization was 36% in patients assigned to CABG and 41% in those assigned to medical therapy (HR, 0.86; 95% CI, 0.72 to 1.04; $P = 0.12$). However, the combined endpoint of death or hospitalization for cardiovascular causes was significantly lower (58%) in the CABG group than in the medical therapy group (68%; HR, 0.74; 95% CI, 0.64 to 0.85; $P < 0.001$) (Fig. 54-17).²⁰⁴ Although preoperative LV dysfunction creates the potential for significant benefit, the perioperative risk should not be underestimated, particularly in the setting of clinical congestive heart failure. Despite the absence of a clear difference in the effect of CABG on patients with greater myocardial viability in the STICH trial,²⁰⁷ selective evaluation of patients for viable myocardium supplied by a reasonable target vessel or vessels for grafting appears to be a reasonable strategy when considering CABG for patients with severe LV dysfunction.²⁰⁸

Myocardial Hibernation (see Chapter 49). Successful reperfusion of viable but noncontractile or poorly contracting myocardium is a goal of coronary revascularization in patients with LV dysfunction. Two related pathophysiologic conditions have been described to explain the reversible ischemic contractile dysfunction: (1) myocardial stunning, or prolonged but temporary postischemic LV dysfunction without myocardial necrosis, and (2) myocardial hibernation, or persistent LV dysfunction when myocardial perfusion is chronically reduced (or repetitively stunned) but sufficient to maintain the viability of tissue. The reduction in myocardial contractility in hibernating myocardium conserves metabolic demands and may be protective, but more prolonged and severe hibernation may lead to severe ultrastructural abnormalities, irreversible loss of contractile units, and apoptosis.

TABLE 54-13 Markers of Viable Myocardium

CLINICAL INDICATOR	DIAGNOSTIC TEST	ALTERNATIVE TEST
Diastolic wall thickness	Echo	CT, CMR
Systolic wall thickening	Echo	CT, CMR, gated SPECT
Regional wall motion	Echo	CT, CMR, gated SPECT
Regional blood flow	SPECT	PET, CMR
Myocardial metabolism	PET	SPECT
Cell membrane integrity	SPECT	PET
Contractile reserve	Dobutamine echo	Angiography, CT, CMR
Myocardial fibrosis	CMR	CT

Echo = echocardiography.

Hibernating myocardium can cause abnormal systolic or diastolic LV function, or both. Studies involving PET, thallium-201, and dobutamine echocardiography have demonstrated that patients with LV dysfunction and evidence of hibernating myocardium have a high mortality rate during medical therapy. The predominant clinical feature of myocardial ischemia in these patients may not be angina but dyspnea secondary to increased LV diastolic pressure. Symptoms of heart failure resulting from chronic LV dysfunction may be inappropriately ascribed to myocardial necrosis and scarring when the symptoms may, in fact, be reversed after the chronic ischemia is relieved by coronary revascularization.

Detection of Hibernating Myocardium. Several clinical markers may be used to determine the likelihood that a dysfunctional myocardial segment is viable or nonviable (Table 54-13). The presence of angina and the absence of Q waves on the ECG and a history of previous MI are useful clues. A severe reduction in the diastolic wall thickness of dysfunctional LV segments is indicative of scarring. On the other hand, akinetic or dyskinetic segments with preserved diastolic wall thickness may represent a mixture of scarred and viable myocardium. Imaging tools that may be used for this assessment (dobutamine echocardiography, PET, contrast-enhanced CMR, CT, and thallium rest-redistribution imaging) are discussed in Chapters 14, 16, and 17.

Surgical Treatment in Special Groups

Women (See Chapter 77)

Women are less likely than men to be referred for coronary angiography and subsequent revascularization.²⁰⁹ In some studies, sex-based differences in referral for revascularization are explained fully by clinical factors. Moreover, it has not been established whether sex-based differences represent inappropriately less consideration of referrals for women, inappropriately more consideration of referrals for men, or both. When compared with men, women who undergo CABG are sicker, as defined by age, comorbid conditions, severity of angina, and history of heart failure. In-hospital mortality and perioperative morbidity after CABG have remained, on average, two times higher in women than in men.²¹⁰ However, when adjusted for the greater risk profile of women referred for CABG, short-term mortality rates, as well as long-term outcomes, are similar to those for men in most, but not all studies. The independent predictors of long-term prognosis in women are similar to those in men and include older age, previous CABG, previous MI, and diabetes.

With generally similar long-term outcomes after surgical revascularization, female sex should not be a significant factor in decisions regarding whether to offer CABG.

Older Patients (see Chapter 76)

A demographic tide in combination with marked improvement in perioperative care and in the outcomes of CABG has resulted in a burgeoning population of elderly patients with extensive CAD undergoing such surgery.²¹¹ The number of individuals older than 75 years in the United States is expected to quadruple in the next 50 years, with cardiovascular disease being the leading cause of

morbidity and mortality in this population. Many such individuals are likely to become candidates for CABG.

Older patients are sicker than their younger counterparts in that they have a greater frequency of comorbid conditions, including peripheral vascular and cerebrovascular disease, more extensive triple-vessel and left main CAD, and a higher frequency of LV dysfunction and history of heart failure.¹⁷⁶ Not unexpectedly, these differences translate into higher perioperative mortality and complication rates, with a sharp increase in the slope of the curve relating mortality to age in patients older than 70 years. Despite these differences, in-hospital mortality for older adults has declined over time to 7% to 9% in those undergoing CABG only and has been reported to be as low as 3% to 4% in the subgroup of octogenarians without significant medical comorbid conditions.²¹² However, elderly patients with high indices of frailty and disability are at significantly higher risk for major morbidity and mortality during CABG.²¹³ Given the marked variation in outcomes in older patients undergoing revascularization, decisions should be based on individual risk and needs assessment.

Renal Disease

Cardiovascular disease is the major cause of mortality in patients with end-stage renal disease (ESRD) and accounts for 54% of deaths (see Chapter 88). Patients with ESRD, as well as those with less severe renal insufficiency, have numerous risk factors that not only accelerate the development of CAD but also complicate its medical management. These risk factors include diabetes, hypertension with LV hypertrophy, systolic and diastolic dysfunction, abnormal lipid metabolism, anemia, and increased homocysteine levels. Therefore mild or more severe renal dysfunction is prevalent in as many as 50% of patients undergoing CABG. Coronary revascularization with PCI or CABG is feasible and well documented in patients with ESRD, but mortality and complication rates are increased.²¹⁴ Patients with milder degrees of renal insufficiency who are not dependent on dialysis are also at higher risk for major perioperative complications, longer recovery times, and lower rates of short-term and midterm survival.²¹⁵ Observational data have suggested that in patients undergoing chronic dialysis, CABG is the preferred strategy for revascularization over PCI.²¹⁴ However, randomized data are few, and 30-day mortality in patients with ESRD undergoing CABG ranges from 9% to as high as 20%.

Patients with Diabetes (see Chapter 61)

Diabetes is an important independent predictor of mortality in patients undergoing surgical revascularization. Patients with diabetes have smaller distal vessels, which are deemed to be poorer targets for bypass grafting.²¹⁶ Nevertheless, the patency of arterial and venous grafts appears to be similar in diabetic and nondiabetic patients. Despite these higher risks with operative intervention, because of the potential long-term benefits of CABG in patients with diabetes and severe CAD, such patients should be considered candidates for CABG (see Comparisons between Percutaneous Coronary Intervention and Coronary Artery Bypass Surgery and Choosing between Percutaneous Coronary Intervention, Coronary Artery Bypass Surgery, and Medical Therapy).²¹⁷

Coronary Bypass Surgery in Patients with Associated Vascular Disease. Management of patients with combined CAD and peripheral vascular disease involving the carotid arteries, the abdominal aorta, or vessels of the lower extremities presents many challenges (see Chapter 58). Combined disease is increasingly becoming frequent as the population of patients under consideration for CABG ages and as technical improvements allow the application of coronary revascularization to ever more complex cases.

Impact of Combined Coronary Artery Disease and Peripheral Vascular Disease. Clinically apparent CAD occurs frequently in patients with peripheral vascular disease. In patients undergoing peripheral vascular surgery, late outcomes are dominated by cardiac causes of morbidity and mortality. Conversely, in patients with CAD the presence of peripheral vascular disease, even if asymptomatic, is associated with an adverse prognosis, presumably because of the greater total atherosclerotic burden borne by these patients.²¹⁸

Because patients with CAD and peripheral atherosclerosis tend to be older and have more widespread vascular disease and end-organ damage than do patients without peripheral atherosclerosis, the perioperative mortality and morbidity consequent to CABG are high and the late outcome is not as favorable. In the Northern New England Cardiovascular data base, in-hospital mortality after CABG was 2.4-fold greater in patients with peripheral vascular disease than in those without it, especially for those with lower extremity disease. Diffuse atheroembolism is a particularly serious complication of CABG in patients with peripheral vascular disease and aortic atherosclerosis. It is a major cause of perioperative death, stroke, neurocognitive dysfunction, and multiorgan dysfunction after CABG.

Peripheral vascular disease is also a strong marker of an adverse long-term outcome.²¹⁸ For example, in the Northern New England Cardiovascular data base, 5-year mortality was approximately twofold greater in patients with peripheral vascular disease than in those without it, even after adjusting for other comorbid conditions, which are more frequent in patients with peripheral vascular disease. Nevertheless, given the diffuse nature of CAD in patients with peripheral vascular disease, CABG may have advantages over PCI in many such patients.

Carotid Artery Disease. In patients with stable CAD and carotid artery disease in whom carotid endarterectomy is planned, exercise stress testing and consideration of coronary revascularization can ordinarily be performed after the carotid surgery. The prevalence of significant carotid disease in an increasingly older population being considered for CABG is high; approximately 20% have a 50% or greater stenosis, 6% to 12% have an 80% or greater stenosis, and the percentage is higher in patients with left main CAD. In patients for whom surgical treatment is being considered for both carotid artery disease and CAD, the merits of a combined versus a staged approach have been debated.^{219,220} Moreover, it remains uncertain whether asymptomatic carotid disease significantly increases the risk for stroke during CABG.²²¹ Neither strategy has been demonstrated to be unequivocally superior to the other, and an individualized approach, depending on the patient's initial condition, severity of symptoms, anatomy of the coronary and carotid vessels, and individual institutional experience, is most appropriate. Preoperative or simultaneous carotid stenting is under investigation as an alternative approach to combined carotid endarterectomy and CABG.²²²

Management of Patients with Associated Vascular Disease (See Chapter 58). Patients with severe or unstable CAD requiring revascularization can be categorized into two groups according to the severity and instability of the accompanying vascular disease. When the noncoronary vascular procedures are elective, they can generally be postponed until the cardiac symptoms have stabilized, either by intensive medical therapy or by revascularization. A combined procedure is necessary in patients with both unstable CAD and an unstable vascular condition, such as frequent recurrent transient ischemic attacks or a rapidly expanding abdominal aortic aneurysm. In some patients in this category, PCI offers the potential for stabilizing the patient's cardiac condition before proceeding with a definitive vascular repair. A problem is posed by the use of clopidogrel after stenting; this will increase bleeding unless surgery is performed at least 5 days after discontinuation of clopidogrel.

Patients Requiring Reoperation

Currently, approximately 12% of coronary artery procedures are reoperations, and in some centers, particularly tertiary care centers, the proportion is increasing rapidly and accounts for 2% of all CABG operations.²²³ The major indication for reoperation is late disease of saphenous vein grafts. An added factor underlying recurrent symptoms is progression of disease in native vessels between the first and second operations. Several series have emphasized the sicker preoperative status of patients undergoing reoperation, including older age, more serious comorbidity, associated valvular heart disease, and a greater prevalence of LV dysfunction and greater extent of ischemic jeopardized myocardium.

Not unexpectedly, the mortality associated with reoperation is significantly higher than that of initial CABG procedures. For patients undergoing first operations, mortality was 2.6% for urgent and 6% for emergency procedures versus 7.4% and 13.5%, respectively, in patients undergoing repeated CABG. Novel approaches to minimize the risk of disrupting patent grafts during reoperation are under investigation.²²⁴

Comparisons between Percutaneous Coronary Intervention and Coronary Artery Bypass Surgery

Observational Studies

Catheter-based revascularizations in most comparative studies have been limited mainly to PTCA, and the findings were largely consistent.¹⁷⁶ Over a period of 1 to 5 years, rates of mortality and nonfatal MI were not significantly different between patients revascularized with CABG versus PTCA, but recurrent events, including angina pectoris and the need for repeat revascularization procedures, were significantly more frequent in the PTCA than in the CABG group, largely as a consequence of incomplete revascularization and restenosis. However, several subgroups of patients who may derive a survival benefit from CABG versus PTCA have been identified and include those with LV dysfunction, probably because of the ability to achieve more complete revascularization with CABG. In addition, CABG provides a survival benefit over that with PTCA when proximal LAD stenosis (>70%) is present.

More recent studies have included patients undergoing stenting. In an analysis of approximately 60,000 patients with multivessel CAD treated with coronary stenting or CABG and recorded in the New York State Registry between 1997 and 2000, CABG was found to be associated with higher survival after adjustment for medical comorbid conditions in patients with two or more diseased vessels, with or without involvement of the LAD coronary artery. Similarly, in an analysis of approximately 600,000 patients with multivessel CAD enrolled in the ACC-NCDR and STS data bases, the observed 1-year mortality rates were similar between patients who underwent CABG and those who underwent PCI. However, 4-year mortality was significantly lower in the CABG group in multiple sensitivity analyses aimed at addressing potential confounders.²²⁵ Nevertheless, the similarity of the unadjusted rates of survival in the New York State Registry highlights the role of clinical judgment in selecting the optimal therapy for the individual patient and the ability to achieve good outcomes in appropriately selected patients with two-vessel CAD, particularly those without involvement of the proximal LAD coronary artery.

Randomized Trials

Overall, the findings from randomized trials indicate that in selected patients with multivessel CAD and preserved ejection fraction, CABG results in fewer repeat revascularizations and fewer symptoms without a significant difference in survival when compared with multivessel PCI.

Percutaneous Coronary Intervention versus Coronary Artery Bypass Surgery in Patients with Single-Vessel Disease.

Both the Lausanne and the MASS (Medicine, Angioplasty, or Surgery Study) trials were limited to patients with isolated disease of the proximal LAD coronary artery.¹⁷⁶ The results of these small trials were consistent in that over a period of 2 to 3 years, rates of mortality and MI were similar in the two treatment arms, as was improvement in symptoms, but at the cost of more frequent reintervention in patients treated with PCI. In a trial comparing minimally invasive direct CABG and stenting in patients with isolated stenosis in the proximal LAD coronary artery (N = 220), patients who underwent CABG were less likely to have recurrent symptoms or undergo repeat revascularization but showed no detectable difference in the risk for death or MI with PCI.

Multivessel Disease. At least 10 published randomized studies have compared PCI with CABG in patients with multivessel CAD. Despite the heterogeneity of the trials in regard to design, methods, and the patient population enrolled, the results are generally comparable and provide a consistent perspective of CABG and PCI in selected patients with multivessel CAD. Nevertheless, there are limitations that should be recognized. Conducted over several decades, the trials evolved substantially with respect to the technology used for both procedures and disease-modifying preventive therapy. Moreover, most patients entered into the trials had well-preserved LV function. Therefore patients enrolled in these trials were at relatively low risk, with predominantly double-vessel CAD and a normal LV ejection fraction—that is, a high proportion of patients in whom CABG had not previously been shown to be superior to medical therapy in regard

to survival. Thus one would not expect a significant mortality difference between PCI and CABG.¹²⁰

With progressive improvements in stent technology, patients with higher-risk coronary anatomy have been enrolled in trials. In the SYNTAX trial conducted between 2005 and 2007, 1800 patients with three-vessel or left main CAD were randomly assigned to undergo CABG or PCI after a “multidisciplinary team” consisting of a local cardiac surgeon and interventional cardiologist determined that equivalent anatomic revascularization could be achieved with either treatment.²²⁶ The primary outcome measure was a noninferiority comparison of the two groups for major adverse cardiac or cerebrovascular events (i.e., death from any cause, stroke, MI, or repeat revascularization) during the 12-month period after randomization. Rates of major adverse cardiac or cerebrovascular events (MACCEs) at 12 months were significantly higher in the PCI group (17.8% versus 12.4% for CABG; $P = 0.002$) (Fig. 54-18), in large part because of an increased rate of repeat revascularization (13.5% versus 5.9%; $P < 0.001$); thus the criterion for noninferiority was not met. At 12 months the rates of death and MI were similar between the two groups. However, stroke was significantly more likely to occur with CABG (2.2% versus 0.6% with PCI; $P = 0.003$).²²⁶ With longer follow-up in this trial, MACCE rates were higher in the PCI group than in CABG-treated patients both at 3 years (20.2% with CABG versus 28.0% with PCI; $P < 0.001$)²²⁷ and at 5 years (26.9% with CABG versus 37.3% with PCI; $P < 0.001$).²²⁸ At 5 years, rates for MI (3.8% with CABG versus 9.7% with PCI; $P < 0.0001$) and repeat revascularization (13.7% with CABG versus 25.9% with PCI; $P < 0.0001$) were significantly increased in the PCI group, whereas rates of all-cause mortality (11.4% with CABG versus 13.9% with PCI; $P = 0.10$) and stroke (3.7% with CABG versus 2.4% with PCI; $P = 0.09$) did not significantly differ between groups. Thus CABG should remain the standard of care for patients with complex coronary lesions (high or intermediate SYNTAX scores), whereas for patients with less complex CAD (low SYNTAX scores) or left main CAD (with low or intermediate SYNTAX scores), PCI remains an acceptable alternative. In a meta-analysis of 10 randomized trials, long-term mortality was similar after CABG or PCI in most subgroups with multivessel CAD. However, CABG appears to be

better in patients with diabetes or older age, where mortality was more favorable in the CABG group.²²⁹ In-hospital costs are lower for patients undergoing PCI, but need for recurrent hospitalization and repeat revascularization procedures over the long term contributes to an increase in postdischarge cost in patients treated with PCI, which resulted in similar overall cost over a 3- to 5-year period.

Patients with Diabetes (see Chapter 61). An initially unexpected finding in the BARI (Bypass Angioplasty Revascularization Investigation) trial was that patients with previously treated diabetes who underwent PTCA had a 5-year mortality of 34.5% versus 19.4% for those who underwent CABG ($P = 0.003$). This advantage of CABG over PTCA for patients with diabetes became more robust by 10 years of follow-up in the BARI trial and was supported in other studies.²³⁰ More rapid progression of atherosclerosis and high rates of restenosis in patients undergoing PCI were plausibly major contributors to this difference. In a collaborative meta-analysis of individual patient data from 7812 patients in 10 trials of PCI versus CABG, total mortality was significantly reduced by 30% with CABG in the subset of 1233 diabetic patients—findings that persisted even after exclusion of the BARI trial.²²⁹

The findings of the BARI-2D trial did not directly compare PCI and CABG but provide additional information and indirect comparisons with respect to revascularization in patients with diabetes mellitus.¹⁷¹ In the BARI-2D trial, 2368 patients with established diabetes and CAD were randomly assigned to prompt revascularization (PCI or CABG) versus delayed/no revascularization and OMT. A notable feature of the prompt-revascularization strategy was prespecification to PCI or CABG before randomization, with patients who had more severe CAD being allocated to CABG. Approximately two thirds of patients in BARI-2D were assigned to PCI, with the remainder who displayed more extensive CAD undergoing CABG based on “heart team” consensus decision making. At the 5-year follow-up, all-cause mortality did not differ between these two treatment groups (Fig. 54-19). However, two prespecified analyses of a secondary composite endpoint (death, MI, or stroke) provide important scientific and clinical insight: (1) when compared with OMT without revascularization, the CABG cohort had a significantly lower rate of death, MI, or stroke

FIGURE 54-18 Outcomes in 1800 patients with SIHD and multivessel CAD randomly assigned to CABG or PCI. **A**, CABG was superior to PCI at 1 year with respect to the primary outcome measure of death from any cause, MI, stroke, or repeat revascularization. **B**, This result was driven by the need for repeat revascularization, which was reduced significantly in the CABG group. **C**, **D**, There was no difference in the rate of death, MI, or stroke or death from any cause in the two treatment groups. (Modified from Serruys PW, Morice MC, Kappetein AP, et al: Percutaneous coronary intervention versus coronary-artery bypass grafting for severe coronary artery disease. *N Engl J Med* 360:961, 2009.)

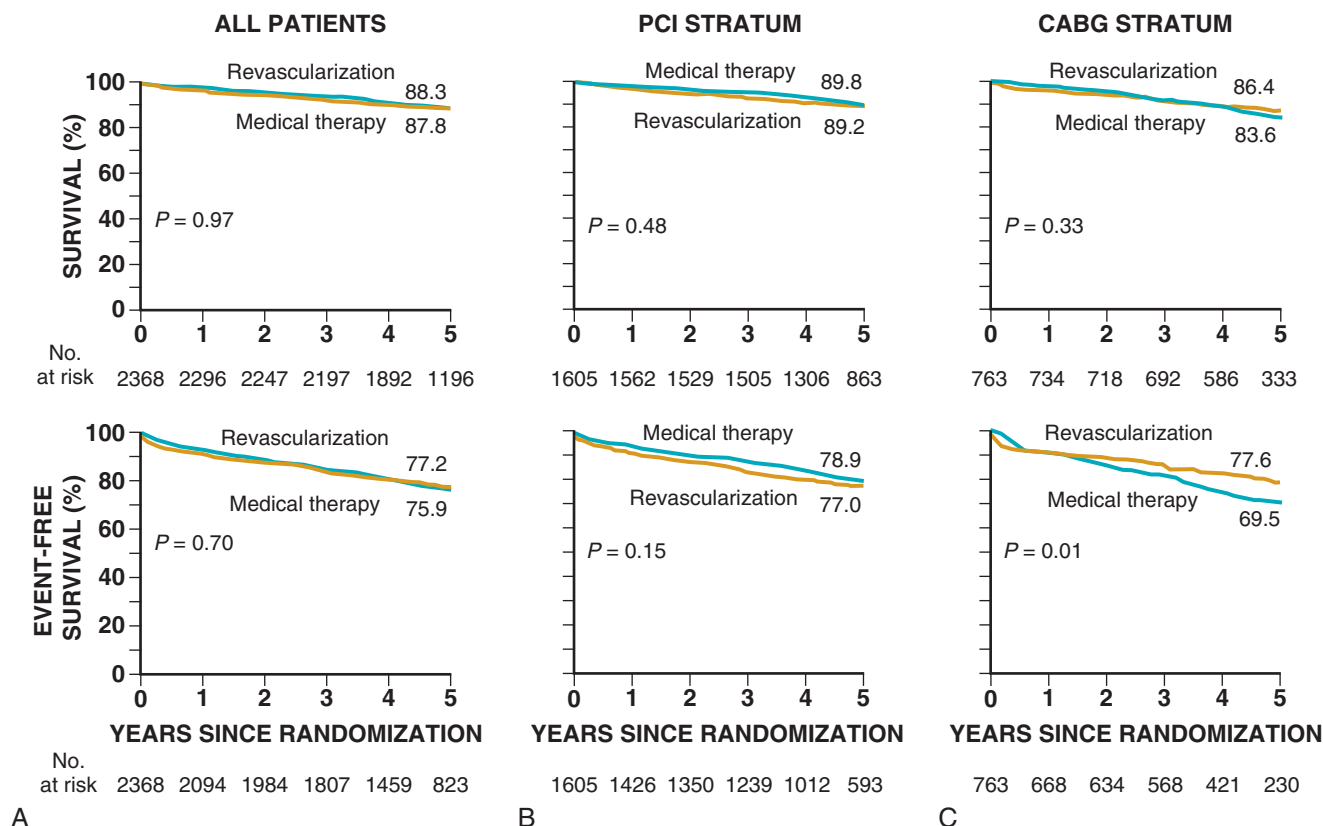

FIGURE 54-19 Outcomes in patients (N = 2368) with type 2 diabetes mellitus and stable CAD assigned to prompt coronary revascularization with CABG or PCI versus intensive medical therapy alone in the BARI-2D trial. Intent to revascularize with PCI or CABG was recorded at the time of randomization. **A**, There was no significant difference in the rates of survival (top) or major cardiovascular events (death, MI, or stroke) (bottom) by treatment group in the overall cohort. **B**, In the PCI, no difference was noted between treatment groups with respect to either endpoint. **C**, In patients selected by the investigator to undergo CABG, the rate of major cardiovascular events was significantly lower in patients who underwent prompt revascularization than in those who underwent medical therapy alone. (Modified from Frye RL, August P, Brooks MM, et al: A randomized trial of therapies for type 2 diabetes and coronary artery disease. *N Engl J Med* 360:2503, 2009.)

driven mainly by a reduction in nonfatal MI but also accompanied by a nonsignificant 16% relative decrease in mortality, and (2) in contrast to CABG, there was absolutely no difference in either the primary survival or secondary composite endpoints in patients treated with PCI or OMT.²³¹ Of note, in BARI-2D only 35% of patients received a DES.

Most recently, the FREEDOM (Future REvascularization Evaluation in patients with Diabetes mellitus: Optimal management of Multivessel disease) trial of 1900 patients with multivessel CAD who were randomly assigned to either DES treatment or CABG has shown a convincing clinical benefit in diabetic patients who underwent CABG. In particular, the trial findings showed significant reductions in all-cause mortality and the composite of death or MI in CABG-treated diabetic patients (Fig. 54-20).²³² The results of the FREEDOM trial add to the growing body of scientific information that patients with SIHD and diabetes, especially those with three-vessel CAD, have better long-term clinical outcomes than do those who undergo PCI with a DES. A smaller randomized trial (VA-CARDS), which similarly compared PCI with a DES versus CABG in patients with SIHD and diabetes, was significantly underpowered (terminated early with only 198 patients randomized) and showed no difference in the rate of the primary endpoint (death or MI) for PCI (25.3%) or CABG (18.4%; $P = 0.73$). However, there was a nominally significant reduction in all-cause mortality with CABG (5.0%) versus PCI (21%), $P = 0.02$.²³³ A potential advantage of CABG over PCI is that bypass grafts to the mid-coronary vessel both treat the culprit lesion (regardless of anatomic complexity) and may afford prophylaxis against new proximal disease progression whereas stents treat only suitable stenotic segments with no benefit against the development of new disease.¹⁷⁴

FIGURE 54-20 Patients (N = 1900) with diabetes and multivessel CAD suitable for revascularization either by PCI or CABG were randomly assigned to undergo either PCI with DESs or CABG and monitored for a minimum of 2 years. The primary endpoint of death, MI, or stroke was significantly lower in the CABG group than in those randomly assigned to PCI (18.7% versus 26.6% at 5 years, $P = 0.005$). Both myocardial infarction and death were significantly reduced with the CABG strategy. However, stroke was more frequent in the CABG group. (From Farkouh ME, Domanski M, Sleeper LA, et al: Strategies for multivessel revascularization in patients with diabetes. *N Engl J Med* 20:367, 2012.)

TABLE 54-14 Comparison of Revascularization Strategies in Multivessel Disease

ADVANTAGES	DISADVANTAGES
Percutaneous Coronary Intervention	
Less invasive	Restenosis
Shorter hospital stay	High incidence of incomplete revascularization
Lower initial cost	Relative inefficacy in patients with severe LV dysfunction
Easily repeated	Less favorable outcome in diabetic persons
Effective in relieving symptoms	Limited to specific anatomic subsets
Coronary Artery Bypass Graft Surgery	
Effective in relieving symptoms	Cost
Improved survival in certain subsets	Morbidity
Ability to achieve complete revascularization	Higher risk for stroke
Wider applicability (anatomic subsets)	

Modified from Faxon DP: Coronary angioplasty for stable angina pectoris. In Beller G, Braunwald E (eds): *Chronic Ischemic Heart Disease. Atlas of Heart Disease. Vol 5*. Philadelphia, WB Saunders, 1995, p 9.15.

Choosing between Percutaneous Coronary Intervention, Coronary Artery Bypass Surgery, and Medical Therapy

Optimal medical therapy for SIHD involves a reduction in reversible risk factors, counseling in lifestyle alteration, treatment of conditions that intensify angina, and pharmacologic management of ischemia. Unlike the situation in ACS patients,⁴⁰ revascularization has not been shown to reduce the rate of death or MI when used in patients with SIHD (with the exception of surgery in patients meeting specific anatomic criteria). Recommendations for either PCI or CABG should be based on both the extent and severity of ischemia (by noninvasive stress testing or by invasive assessment of the hemodynamic significance of anatomic stenosis) and the severity of anginal symptoms or functional impairment. When an unacceptable level of angina persists despite medical management, the patient has troubling side effects from the anti-ischemic drugs, and/or the patient exhibits a high-risk result on noninvasive testing, the coronary anatomy should be defined to allow selection of the appropriate technique for revascularization. Accordingly, based on these data and after elucidation of the coronary anatomy, selection of the technique of revascularization should be made as follows (Table 54-14; see also Fig. e54-4).^{40,176}

Single-Vessel Disease

In patients with single-vessel disease in whom revascularization is deemed necessary and the lesion is anatomicallly suitable, PCI is almost always preferred over CABG.

Multivessel Disease

The first step is to decide whether a patient falls into the category of those who were included in randomized trials comparing PCI and CABG. Most of the patients included in these trials were at lower risk, as defined by double-vessel CAD and well-preserved LV function. Moreover, several trials required that equivalent degrees of revascularization be achievable by both techniques. Most patients with chronically occluded coronary arteries were excluded, and of those who were clinically eligible, approximately two thirds were excluded for angiographic reasons. Despite no significant difference in mortality at 5 years in the SYNTAX trial between PCI- and CABG-treated patients with left main and/or multivessel CAD, rates of both MI and repeat revascularization were significantly higher in patients who underwent PCI.

For patients who either refuse surgery or are not deemed suitable candidates for CABG, PCI remains a reasonable treatment option, provided that the patient accepts the distinct possibility of symptom

recurrence and the need for repeat revascularization. Patients with a single localized lesion in each affected vessel and preserved LV function generally fare best with PCI. Additional anatomic factors, such as the presence of severe proximal LAD disease, should also be considered and weigh in favor of surgery (Fig. e54-4). For patients with left main CAD or severe triple-vessel CAD and LV dysfunction, CABG is generally the best approach.²²⁷ However, in selected patients with left main CAD, excellent technical and clinical results can still be obtained with PCI, but with a greater need for repeated revascularization procedures than with CABG.^{227,234} In general, for all patients with complex multivessel CAD for whom revascularization is being contemplated, there should be a thorough review and discussion of treatment options with the patient by a team that includes a cardiac surgeon and interventional cardiologist to reach a consensus on which approach is best suited for a particular patient.

Need for Complete Revascularization

Complete revascularization is an important goal in patients with LV dysfunction and/or multivessel CAD. The major advantage of CABG over PCI is its greater ability to achieve complete revascularization, particularly in patients with triple-vessel CAD. In most of these patients, especially those with chronic total coronary occlusion, LV dysfunction, or left main CAD, CABG is the procedure of choice. In patients with borderline LV function (ejection fraction between 0.40 and 0.50) and milder degrees of ischemia, PCI may provide adequate revascularization, even if it is not complete anatomically.

In many patients, either method of revascularization is suitable. Other factors to be considered include the following:

1. Access to a high-quality team and operator (surgeon or interventional cardiologist).
2. Patient preference—some patients are reluctant to remain at risk for recurrence of symptoms and reintervention; such patients are better candidates for surgical treatment. Other patients are attracted by the less invasive nature and more rapid recovery from PCI; these patients prefer to have PCI as their initial revascularization with the idea of undergoing CABG if the symptoms persist and/or excellent revascularization has not been achieved.
3. Advanced patient age and comorbidity—frail, very elderly patients and those with comorbid conditions are often better candidates for PCI.
4. Younger patient age—PCI is also often preferable in younger patients (<50 years) with the expectation that they may require CABG at some time in the future and that PCI will postpone the need for surgery; this sequence may be preferable to two operations. Patient preference is a pivotal aspect of the decision to perform PCI or CABG in these groups.

Patients with Diabetes (see Chapter 61)

The BARI-2D trial results reinforced the principal finding of the COURAGE trial that an initial strategy of PCI provides no incremental clinical benefit over OMT, even in patients with diabetes.²³¹ However, in patients who remain symptomatic despite guideline-directed medical therapy or when significant ischemia or extensive CAD is demonstrated, a revascularization strategy is warranted. Either PCI or CABG may be reasonable choices, depending on the anatomic complexity of the disease. However, based on the findings of BARI-2D, FREEDOM, and recent meta-analyses, CABG is regarded as the preferred revascularization approach in patients with multivessel CAD and diabetes when reduction of clinical events is the principal goal of treatment.²¹⁶

Summary of Indications for Coronary Revascularization

1. Certain anatomic subsets of patients are candidates for CABG, regardless of the severity of symptoms or LV dysfunction. Such patients include those with significant left main CAD and most patients with triple-vessel CAD that includes the proximal LAD coronary artery, especially those with LV dysfunction (ejection fraction <50%). Patients with chronic stable angina

- and double-vessel CAD with significant proximal disease of the LAD coronary artery and either LV dysfunction or high-risk findings on noninvasive testing may also be best considered for CABG.¹²⁰
- Despite the absence of definitive improvement in survival in the STICH trial,²⁰⁴ the aggregate evidence supports the benefits of CABG in patients with LV dysfunction and multivessel CAD, regardless of symptoms. In patients whose dominant symptom is heart failure without severe angina, the benefits of coronary revascularization are less well defined, but this approach should be considered in those who also have evidence of severe ischemia (regardless of angina symptoms), particularly in the presence of a significant extent of potentially viable dysfunctional (hibernating) myocardium.¹⁷⁶
 - The primary objective of coronary revascularization in patients with single-vessel disease is relief of significant symptoms or objective evidence of severe ischemia. For most of these patients, PCI is the revascularization modality of choice.
 - In patients with angina who are not considered to be at high risk, survival is similar with surgery, PCI, and medical management.
 - All the indications discussed earlier relate to the potential benefits of CABG over medical therapy on survival. Coronary revascularization with PCI or CABG is highly efficacious in relieving symptoms and may be considered for patients with moderate to severe ischemic symptoms whose condition is not controlled by and/or who are dissatisfied with medical therapy, even if they are not in a high-risk subset. For such patients, the optimal method of revascularization is selected on the basis of LV function and arteriographic findings and the likelihood of technical success.

Other Surgical Procedures for Ischemic Heart Disease

CABG may be combined with surgical procedures aimed at correction of atherosclerotic disease elsewhere in the cardiovascular system, mechanical complications of MI (mitral regurgitation or ventricular septal defect), LV aneurysms, and concomitant valvular heart disease. Not unexpectedly, morbidity and mortality are correspondingly increased because of the added complexity of the procedure and, in many patients who require these other procedures, the presence of underlying LV dysfunction (see later).

Transmyocardial Laser Revascularization

Transmyocardial laser revascularization (TMLR) is performed by placing a laser on the epicardial surface of the left ventricle, exposed through a lateral thoracotomy, and creating small channels from the epicardial to the endocardial surfaces. TMLR has been reported to improve symptoms in patients with refractory angina; however, the failure of two sham-controlled trials of percutaneous laser myocardial revascularization to show any benefit has highlighted the impact of the placebo effect in response to laser myocardial revascularization. The potential to enhance stem cell engraftment has led to new lines of investigation of TMLR in conjunction with stem cell therapy.²³⁵

OTHER MANIFESTATIONS OF CORONARY ARTERY DISEASE

Prinzmetal (Variant) Angina

See Chapters 49 and 53.

Chest Pain with a Normal Coronary Arteriogram

The syndrome of angina or angina-like chest discomfort with normal findings on coronary arteriography, previously termed *syndrome X* (to be differentiated from “metabolic syndrome X,” which is characterized by abdominal obesity, hypertriglyceridemia, low HDL cholesterol, insulin resistance, hyperinsulinemia, and hypertension) (see Chapter 42), is an important clinical entity that is often associated with clinical and electrocardiographic evidence of myocardial ischemia and has previously been underrecognized. Better described as

angina without flow-limiting epicardial coronary stenosis, this syndrome was generally regarded as having a benign long-term prognosis but is now recognized to be associated with an increased risk for adverse outcomes in certain subsets of patients.^{1,2} For decades, angina with normal findings on coronary arteriography in the absence of underlying conditions such as severe aortic stenosis or hypertrophic cardiomyopathy was largely viewed by clinicians as unrelated to true myocardial ischemia but rather a manifestation of undetected noncardiac reasons as an explanation for these symptoms. Potential explanations for angina in the absence of flow-limiting CAD that have historically been offered include vasospastic angina, misinterpretation of the coronary angiogram, potential misdiagnosis of flush (or stump) coronary occlusions at sites of major arterial bifurcations, increased subendocardial pressure leading to coronary artery compression, or hyperdynamic ventricular contraction with an elevated ejection fraction resulting in a supply-demand imbalance. In some patients, particularly premenopausal women, when exercise-induced ST-segment depression during treadmill exercise triggered referral for diagnostic coronary angiography that resulted in normal angiographic findings, these abnormal noninvasive test results were dismissed as being “false positives.” However, steady accumulation of experimental and clinical data has provided a sound scientific basis for recognizing that myocardial ischemia may occur without critical coronary stenoses.^{1,2,236}

Patients with chest pain and normal findings on coronary arteriography may represent as many as 10% to 30% of those undergoing coronary arteriography because of clinical suspicion of angina. This proportion may be substantially higher in women. For example, in the initial WISE (Women’s Ischemic Syndrome Evaluation) study, approximately two thirds of women with chest pain and other findings suggestive of SIHD had no critical coronary stenoses detected with angiography.²³⁶ Data from 388 U.S. hospitals participating in the ACC-NCDR revealed that at least 50% of women and 30% of men referred for coronary angiography had no obstructive CAD.²³⁶ True myocardial ischemia, as reflected by the production of lactate by the myocardium during exercise or pacing, is present in some of these patients. In addition, coronary artery reactivity testing demonstrates evidence of endothelial and microvascular dysfunction in a substantial proportion of such individuals. The incidence of coronary calcification on multislice CT is significantly higher than that in normal controls (53% versus 20%) but lower than that in patients with angina secondary to obstructive CAD (96%). Moreover, observational data have established that their outcome is not as uniformly excellent as suggested by early cohort studies.^{237,238} In addition, abnormal measures of endothelial and microvascular function in these patients are associated with a higher risk for death, MI, or hospitalization for heart failure.²³⁹

The causes of the syndrome are probably multiple and not homogeneous across individuals.^{1,2} Vascular (endothelial and microvascular) dysfunction, coronary vasospasm, and myocardial metabolic abnormalities, as noted above, have each been implicated.^{1,2,236} Included in this syndrome are patients in whom angina may be the direct consequence of subendocardial ischemia as a result of abnormalities in the coronary microvasculature (or arteriolar resistance vessels), the small caliber of which would be beyond the resolution of coronary angiography. This condition is frequently termed microvascular angina. Alternatively, in some individuals, chest discomfort without ischemia may be caused by abnormal pain perception or sensitivity.²⁴⁰ Furthermore, IVUS studies have demonstrated anatomic and physiologic heterogeneity in such patients, with a spectrum ranging from completely normal epicardial coronary arteries to vessels with intimal thickening and atheromatous plaque and non-flow-limiting obstructions (10% to 30% diameter reductions)—insufficient to cause angina on the basis of coronary luminal narrowing alone, but in the setting of superimposed dynamic coronary vasomotor tone, such ischemic symptoms could readily occur. Finally, it may be difficult to distinguish patients with angina and normal findings on coronary arteriography in whom chest pain is caused by ischemia from patients with noncardiac pain. However, an approach of assuming a favorable prognosis and dismissing symptoms in all such patients is clearly not justified by the evidence.^{1,2,236}

Microvascular Dysfunction (Impaired Coronary Flow Reserve). Many patients with evidence of myocardial ischemia do not have visible coronary atherosclerosis at angiography, and conversely, some patients with severe coronary atherosclerotic obstructions neither experience chest discomfort nor have any objective findings of myocardial ischemia. Atherosclerosis is just one element in a complex multifactorial pathophysiologic process that includes inflammation, microvascular coronary dysfunction, endothelial dysfunction, thrombosis, and angiogenesis.^{1,2,236} Accordingly, patients with chest pain, angiographically normal coronary arteries, and no evidence of large-vessel spasm, even after an acetylcholine challenge, may demonstrate an abnormally decreased capacity to reduce coronary resistance and increase coronary flow in response to stimuli such as exercise, adenosine, dipyridamole, and atrial pacing.²⁴¹ These patients also have an exaggerated response of small coronary vessels to vasoconstrictor stimuli and an impaired response to intracoronary papaverine. Abnormal endothelium-dependent vasoreactivity has been associated with regional myocardial perfusion defects on SPECT and PET. It has been reported that patients with angina and angiographically normal coronary anatomy also have impaired vasodilator reserve in forearm vessels and airway hyperresponsiveness, which suggests that the smooth muscle of systemic arteries and other organs may be affected in addition to that of the coronary circulation. Thus there may be features common to both this syndrome and in those who display microvascular angina, subendocardial ischemia, and impaired coronary flow reserve.

Endothelial dysfunction and endothelial cell activation, reported in patients with microvascular angina, may participate in the release of cellular adhesion molecules, proinflammatory cytokines, and constricting mediators that induce changes in the arterial wall and result in microvascular coronary dysfunction and higher risk for the future development of obstructive CAD. Such patients have been observed to have higher levels of circulating intercellular adhesion molecule-1, the vasoconstrictor endothelin-1, and the inflammatory marker hsCRP; moreover, the level of hsCRP appears to correlate with the severity of symptoms and burden of ischemic electrocardiographic changes.

Evidence of Ischemia. Despite the general acceptance that microvascular and/or endothelial dysfunction is present in many patients with angina and normal findings on coronary arteriography, whether ischemia is in fact the putative cause of the symptoms in all patients is not clear. In all probability it would be best to view patients with demonstrable microvascular angina and impaired coronary flow reserve as a subset of the broader group of those with angina and arteriographically normal coronary arteries, but the converse is not true. For this reason, studies of transmyocardial production of lactate have generated mixed results.²⁴² The development of LV dysfunction and electrocardiographic or scintigraphic abnormalities during exercise in some of these patients supports an ischemic cause. Moreover, stress echocardiography with dobutamine detects regional contraction abnormalities consistent with ischemia in a subset of patients. More sensitive techniques, such as perfusion analysis with CMR, have demonstrated that subendocardial perfusion abnormalities, in particular, may be associated with angina with normal angiographic findings.

Abnormal Pain Perception. The lack of definitive evidence of ischemia in many patients with angina and normal coronary angiographic findings has focused attention on alternative nonischemic causes of cardiac-related pain, including a decreased threshold for pain perception—the so-called sensitive heart syndrome.²⁴⁰ This hypersensitivity may result in an awareness of chest pain in response to stimuli such as arterial stretch or changes in heart rate, rhythm, or contractility. A sympathovagal imbalance with sympathetic predominance in some of these patients has also been postulated. At the time of cardiac catheterization, some patients with angina are unusually sensitive to intracardiac instrumentation, with the typical chest pain being consistently produced by direct right atrial stimulation and saline infusion. Measurements of regional cerebral blood flow at rest and during chest pain have suggested differential handling of afferent stimuli between such patients and those with obstructive CAD.

Clinical Features

The syndrome of angina or angina-like chest pain with normal epicardial arteries occurs more frequently in women (see Chapter 77), many of whom are premenopausal, whereas obstructive CAD is found more commonly in men and postmenopausal women.²⁴² Fewer than half of these patients have typical angina pectoris; most have various forms of atypical chest pain. In particular, many women with

microvascular angina will experience dyspnea or fatigue or may have a preponderance of symptoms such as nausea, vomiting, and mid-epigastric pain. Although the features are frequently atypical, the chest pain may nonetheless be severe and disabling. The condition may have markedly adverse effects on quality of life, employment, and use of health care resources.

Physical and Laboratory Examination

Abnormal physical findings reflecting ischemia, such as a precordial bulge, gallop sound, and the murmur of mitral regurgitation, are uncommon in these patients. The resting ECG may be normal, but nonspecific ST-T wave abnormalities are often observed, sometimes occurring in association with the chest pain. Approximately 20% to 30% of patients with chest pain and normal coronary angiographic findings have positive exercise test results. However, many patients with this syndrome do not complete the exercise test because of fatigue or mild chest discomfort. LV function is usually normal at rest and during stress, unlike the situation in obstructive CAD, in which function often becomes impaired during stress.

Prognosis. Accumulating data suggest that the prognosis in patients with chest pain and arteriographically normal coronary arteries is more heterogeneous than once thought. In patients with an ejection fraction of 0.50 or greater in the CASS registry, the 7-year survival rate was 96% for patients with normal arteriographic findings and 92% for those whose arteriographic study revealed mild CAD (50% luminal stenosis). However, subsequent studies have shown that the prognosis is not as favorable in some groups of patients.^{1,2} For example, an ischemic response to exercise is associated with increased mortality.²³⁷ Moreover, in women with angina and no obstructive CAD enrolled in the WISE investigations, persistence of symptoms was associated with more than a twofold higher risk for cardiovascular events.²⁴³ Such patients may be appropriate candidates for formal studies of vascular function and aggressive risk factor modification²⁴² (see also Chapter 77).

Management. In patients with an angina-like chest pain syndrome and normal epicardial coronary arteries, noncardiac causes, such as esophageal abnormalities, should be considered. In patients in whom ischemia can be demonstrated by noninvasive stress testing, a trial of anti-ischemic therapy with nitrates, calcium antagonists, and beta-blocking agents is logical, but the response to this therapy is variable. Perhaps because of the heterogeneity of this population, studies testing these antianginal therapies have produced conflicting results.²⁴² For example, beta blockers may be most effective in such patients who also have evidence of a hyperadrenergic state characterized by increased sympathetic nervous system activity (e.g., hypertension, tachycardia, and reduced heart rate variability). Sublingual nitroglycerin has shown paradoxical effects on blood flow and exercise tolerance in some studies and beneficial effects in others. Alpha-blocking agents have been demonstrated to be ineffective. Observational studies of calcium antagonists have in general resulted in disappointing outcomes with respect to amelioration of symptoms.²⁴² A small pilot study of women with well-documented microvascular angina and myocardial ischemia treated with ranolazine showed an improvement in functional status and quality of life, although this was not a placebo-controlled comparison.¹³⁵

ACE inhibitors have favorable effects on endothelial function, vascular remodeling, and sympathetic tone that may be relevant to the pathophysiology of the underlying myocardial ischemia in some of these patients. Preliminary data on ACE inhibitors in this population are promising. Similarly, estrogen has been shown to attenuate the normal coronary vasomotor responses to acetylcholine, increase coronary blood flow, and potentiate endothelium-dependent vasodilation in postmenopausal women. Studies of estrogen replacement in postmenopausal women with angina but without critical epicardial CAD have demonstrated improvement in symptoms and/or exercise performance; however, the role of exogenous estrogen in treatment of this group remains in question. Finally, treatment with imipramine (50 mg daily) and structured psychological intervention targeted to the altered somatic and visceral pain perception experienced by certain patients have been reported to be helpful in some.²⁴²

Silent Myocardial Ischemia

The prognostic importance and the mechanisms of silent ischemia have been the subject of considerable interest for almost 30 years.²⁴⁴

Epidemiologic studies of sudden death (see Chapter 39), as well as clinical and postmortem studies of patients with silent MI and studies of patients with chronic angina pectoris, have suggested that many patients with extensive coronary artery obstruction never experience angina pectoris in any of its recognized forms (stable, unstable, or variant). These patients may be considered to have a defective anginal warning system in that they may not be subjectively aware of myocardial ischemia when it is present. In addition, up to a third of patients with chronic stable angina also exhibit episodes of silent (asymptomatic) ischemia. The total ischemic burden in these patients refers to the total period of ischemia, both symptomatic and asymptomatic.

Ambulatory Electrocardiography

Ambulatory electrocardiographic monitoring was the diagnostic mainstay to noninvasively assess silent myocardial ischemia in the 1990s and has demonstrated that anginal pain underestimates the frequency of significant cardiac ischemia.²³⁷ The mechanisms underlying the development of ischemia, as detected by ambulatory electrocardiographic and exercise testing, may be different, with concordance between ambulatory electrocardiographic monitoring and SPECT myocardial perfusion imaging being as low as 50%. For identification of silent ischemia, the two techniques probably complement each other.

Transient ST-segment depression of 0.1 mV or more that lasts longer than 30 seconds is a rare finding in normal subjects. In patients with known CAD, such transient ST-segment depression is strongly correlated with independent measurements of impaired regional myocardial perfusion and ischemia, as determined by rubidium-82 uptake measured by PET. In patients with both symptomatic and silent ischemia, perfusion defects occur in the same myocardial regions during symptomatic and asymptomatic episodes of ST-segment depression.

Analysis of ambulatory electrocardiographic recordings in patients with CAD who had both symptomatic and silent myocardial ischemia has shown that 85% of ambulant ischemic episodes occur without chest pain and 66% of angina reports were unaccompanied by ST-segment depression. Their frequency is such that it has been suggested that overt angina pectoris is merely the “tip of the ischemic iceberg.” In patients with SIHD enrolled 1 to 6 months after hospitalization for an acute ischemic event, only 15% had angina with exercise, but 28% had ST-segment depression and 41% had reversible myocardial perfusion defects on thallium scintigraphy. Episodes of silent ischemia have been estimated to be present in approximately one third of all treated patients with angina, although a higher prevalence has been reported in diabetic persons (see Chapter 61). Episodes of ST-segment depression, symptomatic and asymptomatic, exhibit a circadian rhythm and are more common in the morning. Asymptomatic nocturnal ST-segment changes are almost invariably an indicator of double- or triple-vessel CAD or left main coronary artery stenosis.

Pharmacologic agents that reduce or abolish episodes of symptomatic ischemia (e.g., nitrates, beta blockers, calcium antagonists) also reduce or abolish episodes of silent ischemia.

Mechanisms of Silent Myocardial Ischemia. It is not clear why some patients with unequivocal evidence of ischemia do not experience chest pain whereas others are symptomatic. Differences in both peripheral and central neural processing of pain have been proposed as being important factors underlying silent ischemia. PET imaging of cerebral blood flow during painful versus silent ischemia has pointed toward differences in the handling of afferent signals by the central nervous system. Specifically, overactive gating of afferent signals in the thalamus may reduce the cortical activation necessary for perception of pain from the heart. Autonomic neuropathy has also been implicated as a reason for reduced sensation of pain during ischemia, which is why it is believed that diabetic individuals with dysautonomia may more commonly manifest myocardial ischemia without symptoms of angina than nondiabetics people do. Although increased release of endorphins may play a role in some patients with silent ischemia, the results of clinical studies are mixed. Some researchers have suggested that anti-inflammatory cytokines are at play in reducing the inflammatory processes that may participate in the genesis of cardiac pain.

Prognosis. Although some controversy remains, ample evidence has supported the view that episodes of myocardial ischemia,

regardless of whether they are symptomatic or asymptomatic, are of prognostic importance in patients with CAD.^{244,245} In asymptomatic patients, the presence of exercise-induced ST-segment depression has been shown to predict a fourfold to fivefold increase in cardiac mortality in comparison to patients without this finding. Similarly, in patients with stable angina or previous MI, the presence of inducible ischemia, evident by ST-depression or reversible myocardial perfusion abnormalities during exercise testing, is associated with unfavorable outcomes regardless of whether symptoms are present. The strength of this association is greatest when the ischemia is found to occur at a low workload. A study of stress nuclear imaging revealed that a threshold of ischemia in 7.5% or greater of the myocardium was associated with a higher risk for cardiac death or MI in asymptomatic patients without known CAD.²⁴⁶

Substantial improvements in technology have made long-term ambulatory monitoring for ischemia more convenient and reliable with respect to data quality. Nevertheless, whether the incremental prognostic information provided by adding an ambulatory ECG to a standard stress test justifies the cost of using this modality as a tool for widespread screening remains to be determined, but it is unlikely. The exercise ECG can be used to identify most patients likely to have significant ischemia during their daily activities and remains the most important screening test for significant CAD (see Chapter 13). As noted above, however, a substantial percentage of patients with IHD are unable to exercise, and MPI with pharmacologic vasodilator stress has now largely supplanted ambulatory monitoring for ischemia. For this reason, many patients with silent ischemia have been identified because of an asymptomatic positive exercise ECG obtained following MI or as a consequence of a positive scintigraphic perfusion scan undertaken in patients with known angiographic CAD or in asymptomatic subjects with multiple cardiac risk factors (especially diabetes) in whom suspicion of CAD is high. In addition, MPI is widely used to assess symptoms or to identify ischemia in patients with previous revascularization. In such patients with a defective anginal warning system it is reasonable to assume that asymptomatic ischemia has a prognostic significance similar to that of symptomatic ischemia and that their management with respect to disease-modifying preventive therapy, coronary angiography, and revascularization should be similar.

Management. Drugs that are effective in preventing episodes of symptomatic ischemia (e.g., nitrates, calcium antagonists, beta-blocking agents) are also effective in reducing or eliminating episodes of silent ischemia. Coronary revascularization is similarly effective in reducing the rate of both angina and ambulatory ischemia. In the SWISSI-II (Swiss Interventional Study on Silent Ischemia Type II) trial of 201 patients with silent myocardial ischemia who were recovering from acute MI (>2 months), PCI was associated with a significant reduction in late (up to 10-year) mortality when compared with medical therapy,²⁴⁵ but the medical therapy as used in this study was not as intensive as that used in the COURAGE and BARI-2D trials, thus making the results of this fairly small study somewhat difficult to interpret. A recent post hoc analysis of the COURAGE trial evaluated clinical outcomes in patients with silent myocardial ischemia and in those with symptomatic ischemia²⁴⁷ during a 5-year follow-up. A total of 283 patients with SIHD qualified for enrollment on the basis of objective baseline findings of inducible ischemia and significant flow-limiting coronary stenoses (>70%) but who lacked anginal symptoms. When compared with the 1997 symptomatic patients, no major differences were found in the baseline clinical characteristics, nor were there differences in death or MI in comparison to symptomatic patients. However, patients with silent ischemia had significantly fewer hospitalizations for ACS and a lower rate of subsequent revascularization. When outcomes were compared as a function of treatment strategy, no overall differences were detected in patients with silent ischemia between those randomly assigned to PCI or medical therapy for the endpoints of death or MI. However, numerically fewer all-cause deaths occurred in the PCI-treated patients ($n = 7$) than in the medically treated patients ($n = 16$), which was of borderline statistical significance.²⁴⁷ When these results were combined with the ACIP (Asymptomatic Cardiac Ischemia Pilot) trial and the earlier SWISSI-II study, the pooled analysis of 1042 patients with silent ischemia revealed a statistically significant 64% reduction in the composite

endpoint of death or MI in PCI-treated patients and a significant 56% reduction in death alone. Although these data should be interpreted as hypothesis generating, they do suggest that myocardial revascularization may play a potential role in improving prognosis in these patients. However, in contrast, in a propensity-adjusted analysis of patients undergoing repeated revascularization in the setting of asymptomatic ischemia noted on MPI, all-cause mortality was not improved during a mean 5.7-year follow-up.²⁴⁸

In summary, although suppression of ischemia in asymptomatic patients with SIHD appears to be a worthwhile objective, whether treatment should be guided by symptoms or by ischemia as reflected on the ambulatory ECG has not been established. Nevertheless, it seems reasonable to use anti-ischemic pharmacologic therapy in patients with well-documented myocardial ischemia, even if symptoms are lacking. Aggressive secondary prevention with lipid-lowering therapy has also been shown on ambulatory monitoring to reduce ischemia.

Heart Failure in Ischemic Heart Disease (see Chapter 22)

Currently, the leading cause of heart failure in developed countries is CAD.²⁴⁹ In the United States, CAD and its complications account for two thirds to three fourths of all cases of heart failure. In many patients the progressive nature of heart failure reflects the progressive nature of the underlying CAD. The term *ischemic cardiomyopathy* is used for the clinical syndrome in which one or more of the pathophysiologic features just discussed result in LV dysfunction and heart failure symptoms.⁶ This condition is the predominant form of heart failure related to CAD. Additional complications of CAD that may become superimposed on ischemic cardiomyopathy and precipitate heart failure are the development of an LV aneurysm and mitral regurgitation caused by papillary muscle dysfunction.

Ischemic Cardiomyopathy

In 1970, Burch and colleagues first used the term *ischemic cardiomyopathy* to describe the condition in which CAD results in severe myocardial dysfunction, with clinical manifestations often being indistinguishable from those of primary dilated cardiomyopathy (see Chapter 65). Symptoms of heart failure caused by ischemic myocardial dysfunction and hibernation, diffuse fibrosis, or multiple MIs, alone or in combination, may dominate the clinical picture of CAD. In some patients with chronic CAD, angina may be the principal clinical manifestation at one time, but later this symptom diminishes or even disappears as heart failure becomes more prominent. Other patients with ischemic cardiomyopathy have no history of angina or MI (type I silent ischemia), and it is in this subgroup that ischemic cardiomyopathy is most often confused with dilated cardiomyopathy. When angina coexists with ischemic cardiomyopathy, outcomes may be particularly poor.²⁵⁰

It is important to recognize hibernating myocardium in patients with ischemic cardiomyopathy because symptoms resulting from chronic LV dysfunction may be incorrectly thought to result from necrotic and scarred myocardium rather than from a reversible ischemic process.^{208,251} Hibernating myocardium may be present in patients with known or suspected CAD and a degree of cardiac dysfunction or heart failure not readily accounted for by previous MIs.

The outlook for patients with ischemic cardiomyopathy treated medically is poor, and revascularization or cardiac transplantation may be considered.²⁰⁷ The prognosis is particularly poor for patients in whom ischemic cardiomyopathy is caused by multiple MIs, in those with associated ventricular arrhythmias, and in those with an extensive amount of hibernating myocardium. However, this last group of patients, whose heart failure, even if severe, is caused by large segments of reversibly dysfunctional but viable myocardium, may have a better prognosis and relief of heart failure symptoms after revascularization. Thus the key to management of patients with ischemic cardiomyopathy, in addition to providing evidence-based medical therapy for heart failure, is to carefully select patients who

may be appropriate candidates for revascularization. Moreover, meta-analysis of observational studies indicates that CABG can be performed with acceptable operative mortality and 5-year survival in patients with severe LV dysfunction.²⁰⁵

Observational studies have also indicated that assessment of the extent of residual viable myocardium is pivotal to the decision to perform coronary revascularization in patients with ischemic cardiomyopathy. Patients with little or no viable myocardium in whom heart failure is secondary to extensive MI and/or fibrosis should in most cases be managed in a manner similar to those with dilated cardiomyopathy (see Chapters 25 and 65). By contrast, observational studies have suggested that patients with ischemic cardiomyopathy who have extensive multivessel CAD and viable myocardium may derive a survival advantage with CABG. However, the data favoring revascularization in such patients come from older observational studies in which patients did not receive current guideline-directed medical therapy (including beta-blocking agents, ACE inhibitors, and statins). As noted previously, the STICH trial, the largest randomized controlled trial of CABG versus OMT in patients with LV dysfunction, did not show an improvement in its primary endpoint of death from any cause (see Fig. 54-17),²⁰⁴ and viability testing did not appear to identify patients in whom CABG provides a survival benefit.²⁰⁷ However, the secondary endpoint of death from any cause or hospitalization for cardiovascular causes was reduced in the CABG group, 5% versus 68% in the medical therapy group (HR, 0.74; 95% CI, 0.64 to 0.85; $P < 0.001$).²⁰⁴ In addition, in a subsequent observational, propensity-adjusted analysis comparing CABG and medical therapy with respect to survival in patients with an LV ejection fraction less than 0.35, CAD amenable to CABG, and no left main stenosis greater than 50%, a survival advantage was observed through 10 years of follow-up.²⁰⁶ A smaller randomized trial, HEART (Heart Failure Revascularization Trial) was stopped after only 138 of the 800 planned patients were enrolled, thus leaving this question unsettled.^{252,253} Similarly, the small PET and Recovery Following Revascularization-2 (PARR-2) study of 430 patients randomly assigned to PET-guided management versus standard care did not demonstrate an advantage of revascularization when viability testing was used as a guide.²⁵⁴

Additional, rigorous, adequately sized observational studies and randomized controlled trials are needed to determine the efficacy of revascularization versus medical therapy and to define the role of viability testing.

Left Ventricular Aneurysm. LV aneurysm is usually defined as a segment of the ventricular wall that exhibits paradoxical (dyskinetic) systolic expansion. Chronic fibrous aneurysms interfere with LV performance principally through loss of contractile tissue. Aneurysms made up largely of a mixture of scar tissue and viable myocardium or of thin scar tissue also impair LV function by a combination of paradoxical expansion and loss of effective contraction.²⁵⁵ False aneurysms (pseudoaneurysms) represent localized myocardial rupture in which the hemorrhage is limited by pericardial adhesions, and they have a mouth that is considerably smaller than the maximal diameter (Fig. e54-5). True and false aneurysms may coexist, although the combination is extremely rare.

The frequency of LV aneurysms depends on the incidence of transmural MI and heart failure in the population studied. LV aneurysms and the need for aneurysmectomy have declined dramatically during the past 5 to 10 years in concert with the expanded use of acute reperfusion therapy for evolving MI (see Chapter 52). More than 80% of LV aneurysms are located anterolaterally near the apex. They are often associated with total occlusion of the LAD coronary artery and poor collateral blood supply. Approximately 5% to 10% of aneurysms are located posteriorly. Three fourths of patients with LV aneurysms have multivessel CAD.

Approximately 50% of patients with moderate or large aneurysms have symptoms of heart failure, with or without associated angina, approximately 33% have severe angina alone, and approximately 15% have symptomatic ventricular arrhythmias that may be intractable and life-threatening. Mural thrombi are found in almost half of patients with chronic LV aneurysms and can be detected by angiography and two-dimensional echocardiography (see Chapter 14). Systemic embolic events in patients with thrombi and an LV aneurysm tend to

FIGURE e54-5 Hearts in systole and diastole with true and false anatomic and functional left ventricular aneurysms and healed MI. A normal heart in systole and diastole is shown for comparison (**inset**). **A**, A true anatomic left ventricular aneurysm protrudes during both systole and diastole, has a mouth that is as wide as or wider than the maximal diameter, has a wall that was formerly the wall of the left ventricle, and is composed of fibrous tissue with or without residual myocardial fibers. A true aneurysm may or may not contain thrombus and almost never ruptures once the wall is healed. **B**, A false anatomic left ventricular aneurysm protrudes during both systole and diastole, has a mouth that is considerably smaller than the maximal diameter of the aneurysm and represents a myocardial rupture site, has a wall made up of parietal pericardium, almost always contains thrombus, and often ruptures. A functional left ventricular aneurysm protrudes during ventricular systole but not during diastole and consists of fibrous tissue with or without myocardial fibers. Ao = aorta; LA = left atrium; LV = left ventricle. (From Cabin HS, Roberts WC: Left ventricular aneurysm, intra-aneurysmal thrombus, and systemic embolus in coronary heart disease. *Chest* 77:586, 1980.)

occur early after MI. In patients with a chronic LV aneurysm (documented at least 1 month after MI), subsequent systemic emboli were extremely uncommon (0.35 per 100 patient-years in those not receiving anticoagulants).

Detection. Clues to the presence of an aneurysm include persistent ST-segment elevations on the resting ECG (in the absence of chest pain) and a characteristic bulge of the silhouette of the left ventricle on a chest roentgenogram. Marked calcification of the LV silhouette may be present. These findings, when clear-cut, are relatively specific, but they have limited sensitivity. Radionuclide ventriculography and two-dimensional echocardiography can demonstrate LV aneurysms more readily; the latter is also helpful in distinguishing between true and false aneurysms based on the demonstration of a narrow neck in relation to cavity size in the latter. Color flow echocardiographic imaging is useful in establishing the diagnosis because flow “in and out” of the aneurysm, as well as abnormal flow within the aneurysm, can be detected, and subsequent pulsed Doppler imaging can reveal a “to-and-fro” pattern with characteristic respiratory variation in the peak systolic velocity. CMR may be emerging as the preferred noninvasive technique for the preoperative assessment of LV shape, thinning, and resectability.²⁵⁶

Left Ventricular Aneurysmectomy. True LV aneurysms do not rupture, and operative excision is carried out to improve the clinical manifestations, most often heart failure but sometimes also angina, embolization, and life-threatening tachyarrhythmias.²⁵⁷ CABG is frequently performed along with aneurysmectomy, especially in patients in whom angina accompanies heart failure.

A large LV aneurysm in a patient with symptoms of heart failure, particularly if angina pectoris is also present, is a possible indication for surgery. The operative mortality rate for LV aneurysmectomy is approximately 8% (ranging from 2% to 19%), with rates as low as 3% being reported in more recent series. Improvement in LV function has been reported in survivors of resection of LV aneurysms. Anterior ventricular restoration has the potential to reverse the adverse remodeling, realign contractile fibers, and decrease LV wall stress and has thus been of interest as a possible intervention to mitigate the progression of ischemic cardiomyopathy. Small, unblinded series have suggested that surgical ventricular restoration (SVR) could result in improvement in both LV function and quality of life.²⁵⁸

The value of surgical therapy, including SVR, for patients with ischemic cardiomyopathy who do not have frank LV aneurysms was tested in the STICH trial. In the first report from this study, SVR failed to confer any benefit when added to CABG in patients with heart failure, dilated left ventricles, and severe regional wall motion abnormalities.²⁵⁹ To be included, patients had to have an ejection fraction lower than 35%, CAD amenable to CABG, and an area of severe regional dysfunction in the LV anterior wall. Patients were randomly assigned to receive CABG alone ($n = 499$) or CABG plus SVR ($n = 501$). Both surgical interventions improved symptoms of heart failure and exercise capacity, and SVR reduced the end-systolic volume index by 20% versus 3% with CABG at a median follow-up of 4 years; however, no difference was observed between the two groups in combined rates of death or cardiac hospitalization: 56% for CABG and 57% for CABG plus SVR. Thus in the absence of new data, use of SVR remains an unproven strategy in the management of patients with heart failure.²⁵⁸

Mitral Regurgitation Secondary to Coronary Artery Disease

Mitral regurgitation is an important cause of heart failure in some patients with CAD. Rupture of a papillary muscle or the head of a papillary muscle usually causes severe acute mitral regurgitation in the course of acute MI (see Chapters 51 and 63). The cause of chronic mitral regurgitation in patients with CAD is multifactorial, and the geometric determinants are complex; these include papillary muscle dysfunction from ischemia and fibrosis in conjunction with a wall motion abnormality and changes in LV shape in the region of the papillary muscle and/or dilation of the mitral annulus.²⁶⁰ Enlargement of the mitral annulus at end-systole is asymmetric, with lengthening primarily involving the posterior annular segments and leading to prolapse of leaflet tissue tethered by the posterior papillary muscle and restriction of leaflet tissue attached to the anterior leaflet. Most patients with chronic CAD and mitral regurgitation have previously suffered an MI. Clinical features that help identify mitral regurgitation secondary to papillary muscle dysfunction as the cause of acute

pulmonary edema or of milder symptoms of left-sided heart failure include a loud systolic murmur and demonstration of a flail mitral valve leaflet on echocardiography.

In some patients with severe mitral regurgitation into a small, non-compliant left atrium, the murmur may be unimpressive or inaudible. Doppler echocardiography is helpful in assessing the severity of the regurgitation (see Chapter 14). As in mitral regurgitation of other causes, the left atrium is not usually greatly enlarged unless mitral regurgitation has been present for more than 6 months. The ECG is nonspecific, and most patients have angiographic evidence of multivessel CAD.

Management

In patients with severe mitral regurgitation, the indications for surgical correction, usually in association with CABG, are fairly clear-cut.²⁶¹ Mitral valve repair is not always durable, however, because of progression of the underlying LV dysfunction, and randomized data from the NHLBI Cardiothoracic Surgery Network (CTSN) have shown that mitral replacement is equivalent to repair in producing reverse LV remodeling and results in more durable correction.²⁶² The decision is based on the anatomic characteristics of the structures forming the mitral valve apparatus, the urgency of the need for surgery, and the severity of LV dysfunction. A more complex and frequently encountered problem involves the indications for mitral valve surgery in patients undergoing a CABG procedure in whom the severity of mitral regurgitation is moderate.²⁶³ The decision is based partly on the presence or absence of structural abnormalities of the mitral apparatus and the amenability of the valve to repair. Intraoperative transesophageal echocardiography is invaluable in assessing the severity of regurgitation, the reparability of the valve, and the success of the integrity of the repair after discontinuation of CPB (see Chapter 14). Surgical revascularization and repair appear to be favorable over PCI in patients with multivessel CAD and significant mitral regurgitation.²⁶⁴ The NHLBI CTSN has developed a second ongoing randomized clinical trial to identify the role of mitral valve surgery at the time of CABG in patients with moderate ischemic mitral regurgitation.²⁶⁵

The mortality associated with combined CABG and mitral valve replacement in the 2005 STS database was approximately 10%. For bypass surgery and mitral valve repair, mortality in 2011 was less than 6% overall, including emergency and reoperative procedures.¹⁹⁰ Predictors of early mortality include the need for replacement versus repair (in some but not all series) but, in addition, may include other variables such as age, comorbid conditions, the urgency of surgery, and LV function. Late results are strongly influenced by the pathophysiologic mechanisms underlying mitral regurgitation and are poorer in patients with regurgitation resulting from annular dilation or restrictive leaflet motion than in patients with chordal or papillary muscle rupture. It is encouraging that despite the relatively high operative mortality, late survival of hospital survivors is excellent. In patients with very poor LV function and dilation of the mitral annulus, mitral regurgitation can intensify the severity of LV failure. In such patients the risk associated with surgery is high and the long-term benefit is not established, and a trial of intensive medical therapy, including afterload reduction, beta blockade, and biventricular pacing (see Chapters 25 and 26) may be worthwhile because favorable remodeling may reduce the severity of mitral regurgitation without the need for surgery. For patients undergoing CABG, the procedural risks associated with combined CABG and mitral valve repair may outweigh the benefit of reduced mitral regurgitation in those at highest perioperative risk.²⁶¹

Cardiac Arrhythmias. In some patients with CAD, cardiac arrhythmias are the dominant clinical manifestation of the disease. Various degrees and forms of ventricular ectopic activity are the most common arrhythmias in patients with CAD, but serious ventricular arrhythmias may be a major component of the clinical findings in other subgroups. The clinical features of arrhythmias and their management in patients with CAD are discussed in Chapters 34 and 35.

Nonatheromatous Coronary Artery Disease. Although atherosclerosis is by far the most common cause of CAD, other conditions

may also be responsible. The most common causes of nonatheromatous CAD resulting in myocardial ischemia are the syndrome of angina-like pain with normal coronary arteriographic findings and Prinzmetal angina (see Chapters 49 and 53).

Nonatheromatous CAD may result from other diverse abnormalities, including congenital abnormalities in the origin or distribution of the coronary arteries (see Chapters 20 and 62). The most important of these abnormalities are anomalous origin of a coronary artery (usually the left) from the pulmonary artery, origin of both coronary arteries from either the right or the left sinus of Valsalva, and coronary arteriovenous fistula.²⁶⁶ An anomalous origin of the left main coronary artery or right coronary artery from the aorta, with subsequent coursing between the aorta and pulmonary trunk, is a rare and sometimes fatal coronary arterial anomaly. Coronary anomalies are reported to cause between 12% and 19% of sports-related deaths in U.S. high school and college athletes and account for a third of cardiac anomalies in military recruits with nontraumatic sudden death.

Myocardial Bridging. This cause of systolic compression of the LAD coronary artery is a well-recognized angiographic phenomenon of questionable clinical significance.²⁶⁷

Connective Tissue Disorders. Several inherited connective tissue disorders are associated with myocardial ischemia (see Chapter 8), including Marfan syndrome (causing aortic and coronary artery dissection), Hurler syndrome (causing coronary obstruction), homocystinuria (causing coronary artery thrombosis), Ehlers-Danlos syndrome (causing coronary artery dissection), and pseudoxanthoma elasticum (causing accelerated CAD). Kawasaki disease, a mucocutaneous lymph node syndrome, may cause coronary artery aneurysms and ischemic heart disease in children.

Spontaneous Coronary Dissection. This is a rare cause of MI and sudden cardiac death. Chronic dissection manifested as heart failure has been described. In one series, approximately 75% of cases were diagnosed at autopsy and 75% occurred in women, half of which were associated with a postpartum state. Some cases are associated with atherosclerosis. Hypertension has been postulated as a cause of multivessel spontaneous coronary dissection in some patients, whereas in others, no obvious cause has been identified. In the acute phase, thrombolytic therapy may be dangerous, but early angiography may identify patients who could benefit from stenting or CABG.²⁶⁸ In survivors of spontaneous coronary artery dissection, the subsequent 3-year mortality was 20%, but complete healing as defined angiographically may lead to a favorable outcome without intervention. Newer coronary imaging modalities may be useful for characterizing coronary dissection.²⁶⁹

Coronary Vasculitis. This condition, which results from connective tissue diseases or autoimmune forms of vasculitis, including polyarteritis nodosa, giant cell (temporal) arteritis, and scleroderma, has been well described (see Chapter 84). Coronary arteritis is seen at autopsy in approximately 20% of patients with rheumatoid arthritis but is rarely associated with clinical manifestations. The incidence of CAD is increased in women with systemic lupus erythematosus (SLE). In patients with SLE, CAD has been attributed to vasculitis, immune complex-mediated endothelial damage, and coronary thrombosis from antiphospholipid antibodies, as well as accelerated atherosclerosis. A giant coronary artery aneurysm in patients with SLE is an unusual manifestation that has been associated with the development of acute MI despite therapy. Antiphospholipid syndrome, characterized by arterial and venous thrombosis and the presence of antiphospholipid antibodies, may be associated with MI, angina, and diffuse LV dysfunction.

Takayasu Arteritis. In rare cases (see Chapter 84), this condition is associated with angina, MI, and cardiac failure in patients younger than 40 years. Coronary blood flow may be decreased by involvement of the ostia or proximal segments of the coronary arteries, but disease in distal coronary segments is rare. The average age at the onset of symptoms is 24 years, and the event-free survival rate 10 years after diagnosis is approximately 60%. Luetic aortitis may also produce myocardial ischemia by causing coronary ostial obstruction. CT angiography has been shown to be useful in detecting involvement of the coronary arteries in Takayasu arteritis.²⁷⁰

Postmediastinal Irradiation. The occurrence of CAD and morbid cardiac events in young persons after mediastinal irradiation is highly suggestive of a cause-and-effect relationship.²⁷¹ Pathologic changes include adventitial scarring and medial hypertrophy with severe intimal atherosclerotic disease. Radiation injury may be latent and may not be manifested clinically for many years after therapy. Contributory factors include higher doses than those currently administered and the presence of cardiac risk factors. In patients without risk factors

who receive an intermediate total dose of 30 to 40 Gy, the risk for cardiac death and MI is low.

Myocardial ischemia not caused by coronary atherosclerosis can also be a result of embolism from infective endocarditis (see Chapter 64), implanted prosthetic cardiac valves (see Chapter 63), calcified aortic valves, mural thrombi, and primary cardiac tumors.

Cocaine (See Chapter 68). Because of its widespread use, cocaine has become a well-documented cause of chest pain, MI, and sudden cardiac death. In a population-based study of sudden death in persons 20 to 40 years of age in Olmsted County over a 30-year period, a high prevalence of cocaine abuse was observed in the more recent cohort of young adults who died suddenly. The principal effects of cocaine are mediated by alpha-adrenergic stimulation, which causes an increase in myocardial O₂ demand and a reduction in O₂ supply because of coronary vasoconstriction (see Chapter 49).²⁷²

Cardiac Transplantation–Associated Coronary Arteriopathy

See Chapters 28 and 41.

FUTURE PERSPECTIVES

Despite the fact that Heberden aptly described angina almost two and a half centuries ago, our understanding of the syndrome, its causes, and optimal management continue to evolve. We wish to highlight three major areas in need of continued investigation. First, the complex and probably heterogeneous causes of myocardial ischemia require continued exploration. We are now confronted by substantial data challenging the paradigm that IHD requires critical epicardial coronary atherosclerosis or other structural heart disease that results in dramatically increased myocardial O₂ demand. Preclinical, translational, and clinical epidemiologic data have all demonstrated abnormalities in coronary artery function that may result in myocardial ischemia in the absence of atherosclerotic obstruction. However, as yet, therapies proposed to address this important syndrome appear to be insufficient. Additional insight into the pathobiology of ischemia in these circumstances may lead to new therapeutic directions. Second, although it is clear that an initial approach of guideline-directed secondary preventive medical therapy and coronary revascularization when necessary is the best approach for most patients with SIHD, there are subsets of patients with indicators of particularly high risk for whom coronary revascularization would seem logical. However, clinical equipoise remains regarding whether such patients, including those with moderate or severe ischemia on noninvasive testing, should routinely undergo coronary revascularization in the absence of symptoms that are refractory to medical therapy. Third, definitive evidence to guide the management of patients with SIHD and other structural heart disease, in particular, concomitant LV dysfunction and mitral valvular disease, remains elusive. In our view, complete revascularization, usually surgical, remains reasonable for patients with multivessel CAD, LV dysfunction, and viable myocardium, particularly when objective evidence of ischemia is present. However, recent studies have challenged this view. Despite our wealth of experience with SIHD, important unanswered questions remain.

GUIDELINES

Stable Ischemic Heart Disease

David A. Morrow and William E. Boden

The American College of Cardiology Foundation and the American Heart Association (ACCF/AHA) published updated guidelines for the diagnosis and management of patients with stable ischemic heart disease (SIHD) in 2012.¹ Populations addressed include patients with "ischemic equivalents" such as dyspnea or arm pain with exertion and patients with IHD who have become asymptomatic, including those who have undergone revascularization procedures. Patients with unstable ischemic syndromes are not included in these guidelines (see the guidelines summarized in [Chapter 53G](#)). As with other ACCF/AHA guidelines, indications for interventions are classified into the following four groups:

Class I—for generally accepted indications

Class IIa—when indications are controversial but the weight of evidence is supportive

Class IIb—when usefulness or efficacy is less well established

Class III—when there is consensus against the usefulness of the intervention

The guidelines use a convention for rating levels of evidence on which the recommendations have been based, as follows:

Level A—derived from data from multiple randomized clinical trials

Level B—derived from a single randomized trial or nonrandomized studies

Level C—based on the consensus opinion of experts or standard of care

OVERVIEW

The ACCF/AHA guidelines emphasize the importance of a detailed symptom history, focused physical examination, and directed risk factor assessment for patients with chest pain to estimate the probability of IHD before additional testing. For patients without symptoms or findings suggestive of high risk, noninvasive evaluation rather than invasive coronary angiography is recommended ([Fig. 54G-1](#)). For patients with an intermediate or high probability of coronary artery disease (CAD), clinicians should exclude unstable ischemic syndromes and conditions that might exacerbate or cause angina. If these are not present, noninvasive testing should be considered to refine the diagnostic assessment of patients with an intermediate probability of CAD ([Fig. 54G-1](#)) and to perform risk stratification in patients with a high probability of or established SIHD ([Fig. 54G-2](#)).

The treatment algorithm recommended by the ACCF/AHA guidelines emphasizes the importance of patient education about CAD, prevention of progression of atherosclerosis through risk factor management, and improvement in health status by treatment of ischemic symptoms ([Fig. 54G-3](#)). In particular, the patient should be included

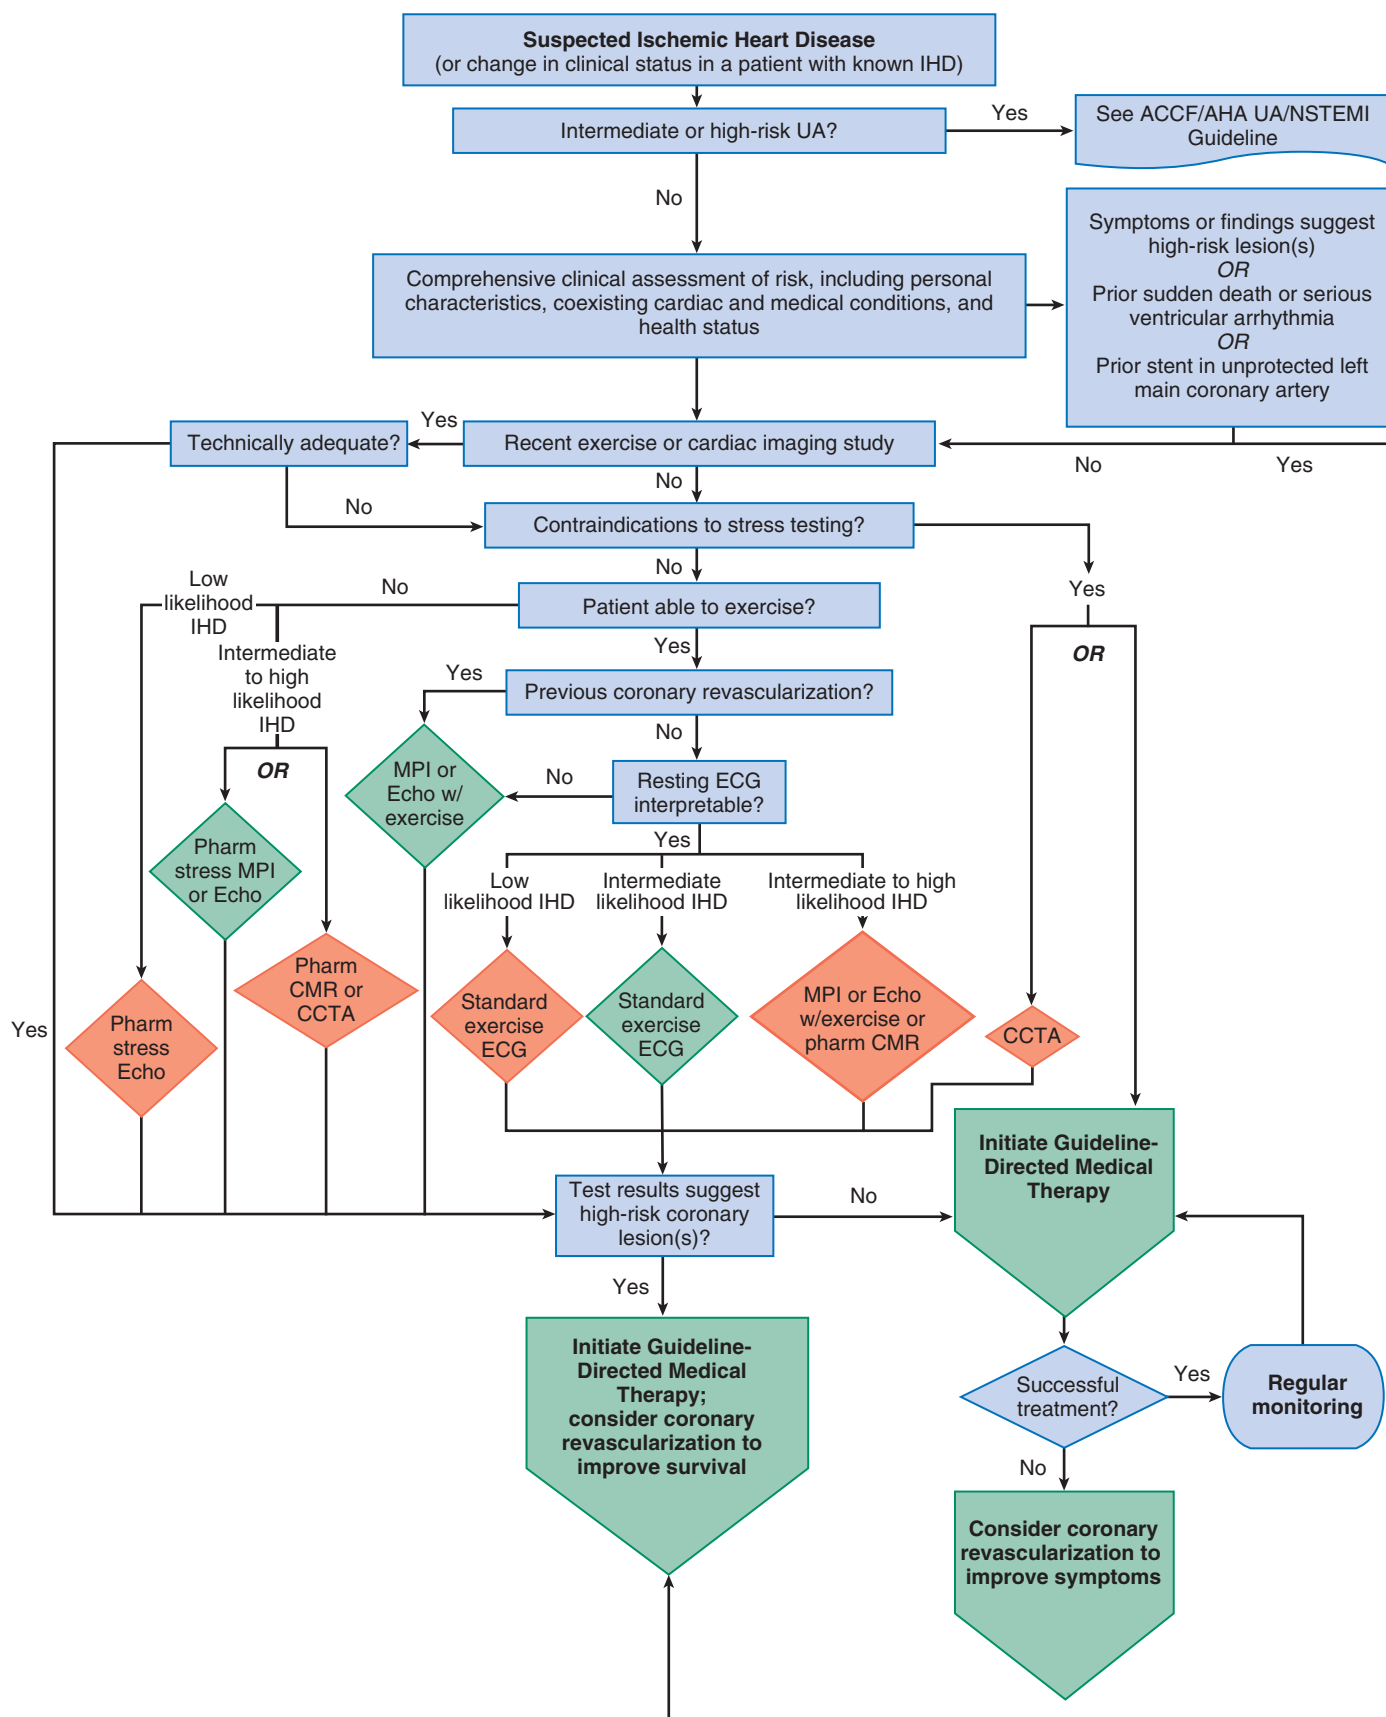

FIGURE 54G-1 Diagnosis of patients with suspected SIHD. Colors correspond to the class of recommendations: green = class 1; orange = class IIa. The algorithms do not represent a comprehensive list of recommendations (see full guidelines for all recommendations). CCTA is reasonable only for patients with an intermediate probability of IHD. CCTA = cardiac computed tomography angiography; CMR = cardiac magnetic resonance (imaging); ECG = electrocardiography; Echo = echocardiography; MPI = myocardial perfusion imaging; NSTEMI = non-ST-segment elevation myocardial infarction; Pharm = pharmacologic; UA = unstable angina. (From Fihn SD, Gardin JM, Abrams J, et al: 2012 ACCF/AHA/ACP/AATS/PCNA/SCAI/STS guideline for the diagnosis and management of patients with stable ischemic heart disease: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, and the American College of Physicians, American Association for Thoracic Surgery, Preventive Cardiovascular Nurses Association, Society for Cardiovascular Angiography and Interventions, and Society of Thoracic Surgeons. *J Am Coll Cardiol* 60:2564, 2012.)

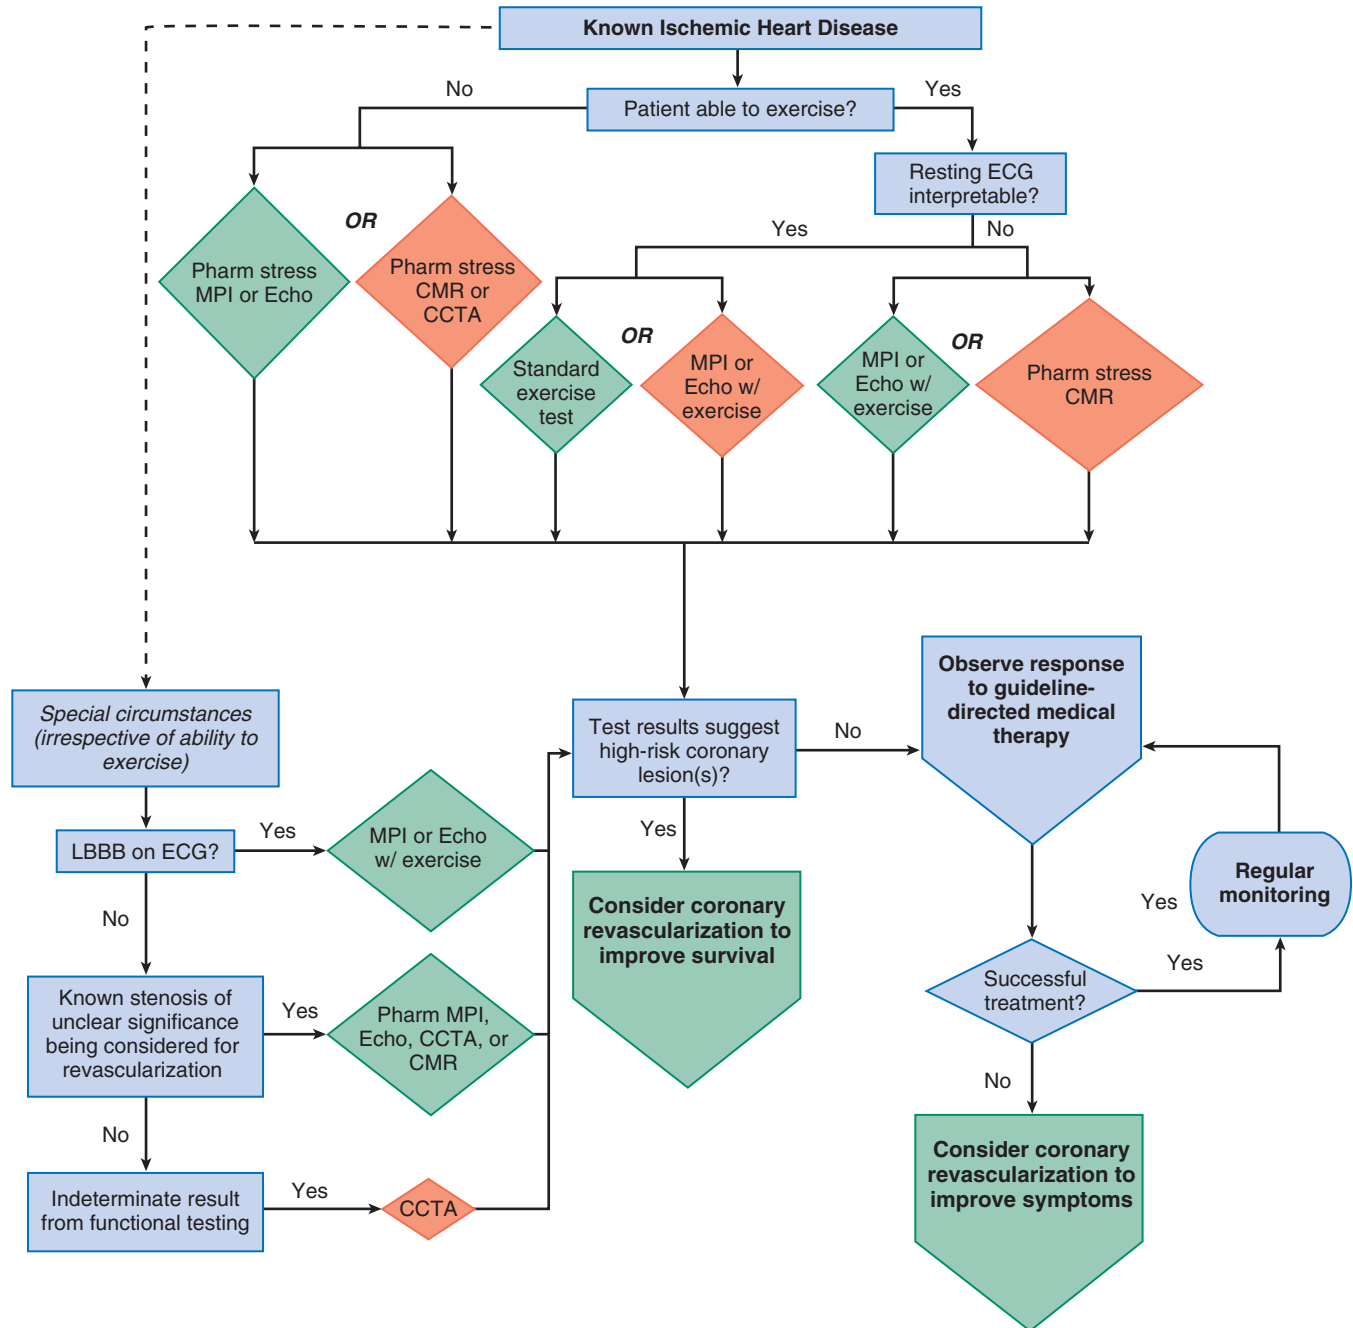

FIGURE 54G-2 Algorithm for risk stratification in SIHD. The algorithms do not represent a comprehensive list of recommendations (see full guideline text for all recommendations). Echo = echocardiography; Pharm = pharmacologic. (From Fihn SD, Gardin JM, Abrams J, et al: 2012 ACCF/AHA/ACCP/AATS/PCNA/SCAI/STS guideline for the diagnosis and management of patients with stable ischemic heart disease: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, and the American College of Physicians, American Association for Thoracic Surgery, Preventive Cardiovascular Nurses Association, Society for Cardiovascular Angiography and Interventions, and Society of Thoracic Surgeons. *J Am Coll Cardiol* 60:2564, 2012.)

in decision making such that choices about diagnostic and therapeutic options are made through a process of shared decision making involving the patient and provider, with discussion of risks, benefits, and costs to the patient.

DIAGNOSIS

Noninvasive Studies Resting Electrocardiography

A resting electrocardiogram (ECG) is recommended in patients undergoing evaluation for symptoms who do not have an obvious, noncardiac cause of chest pain. Any of the following abnormalities on the ECG are associated with a poorer prognosis: evidence of

previous myocardial infarction (MI); persistent ST-segment depression or T wave inversion (especially in leads V_1 to V_3); left bundle branch block (LBBB), bifascicular block, or high-degree atrioventricular block; or left ventricular (LV) hypertrophy.¹

Exercise Electrocardiography

Exercise testing is considered most valuable for diagnosis when the patient's other clinical data suggest an intermediate probability of CAD. The ACCF/AHA guidelines recommend the use of exercise ECGs for such patients unless the baseline ECG shows abnormalities likely to render the exercise tracing uninterpretable or they are unable to exercise (see Fig. 54G-1). In addition, the guidelines support an exercise ECG as being reasonable in patients with a low pretest probability of obstructive CAD who do require testing (Table 54G-1).

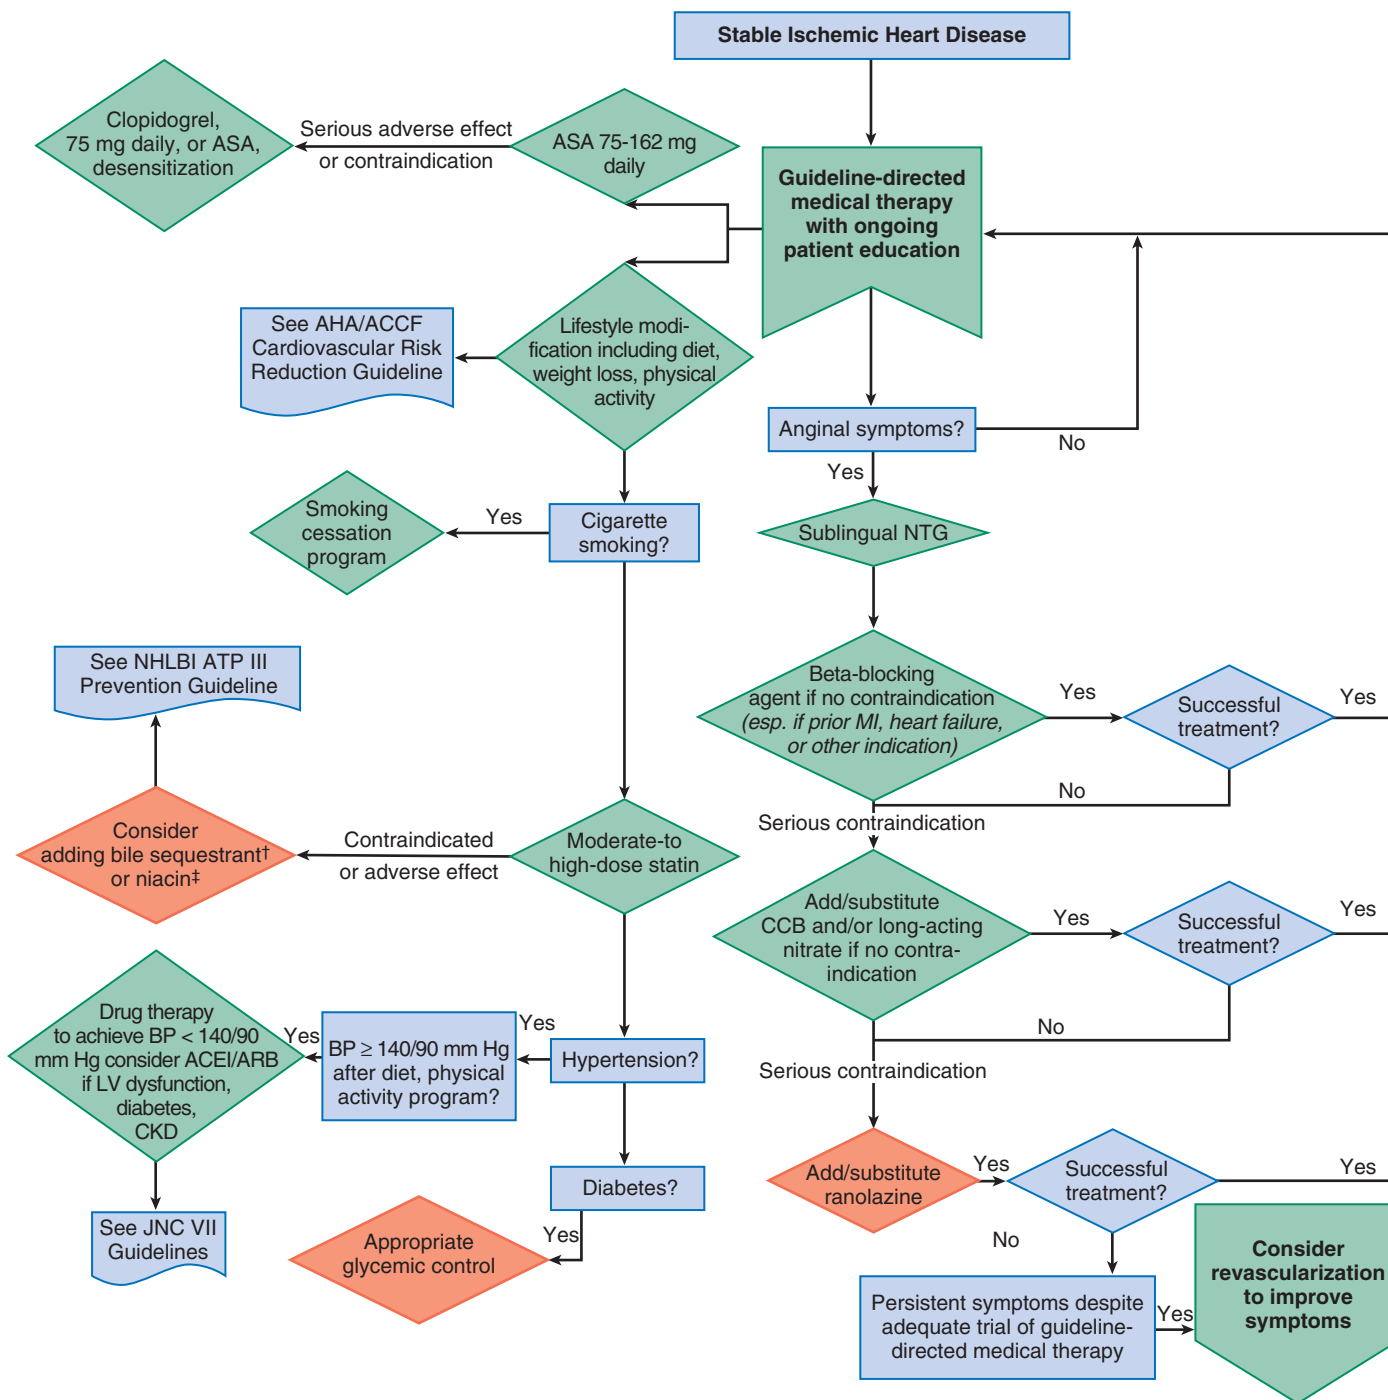

FIGURE 54G-3 Algorithm for guideline-directed medical therapy for patients with SIHD. The algorithms do not represent a comprehensive list of recommendations (see full guideline text for all recommendations). †Use of a bile acid sequestrant is relatively contraindicated when the triglyceride level is 200 mg/dL or higher and is contraindicated when it is 500 mg/dL or higher. ‡Dietary niacin supplement must not be used as a substitute for prescription niacin. ACEI = angiotensin-converting enzyme inhibitor; ARB = angiotensin receptor blocking agent; ASA = aspirin, ATP III = Adult Treatment Panel III; BP = blood pressure; CCB = calcium channel blocking agent; CKD = chronic kidney disease; JNC VII = Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure; NHLBI = National Heart, Lung and Blood Institute; NTG = nitroglycerin. (From Fihn SD, Gardin JM, Abrams J, et al: 2012 ACCF/AHA/ACP/AATS/PCNA/SCAI/STS guideline for the diagnosis and management of patients with stable ischemic heart disease: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, and the American College of Physicians, American Association for Thoracic Surgery, Preventive Cardiovascular Nurses Association, Society for Cardiovascular Angiography and Interventions, and Society of Thoracic Surgeons. *J Am Coll Cardiol* 60:2564, 2012.)

Stress Imaging Studies

The ACCF/AHA guidelines recommend stress imaging (exercise or pharmacologic) as opposed to an exercise ECG when the ECG is uninterpretable, such as in (1) patients who have complete LBBB, electronically paced ventricular rhythm, preexcitation (Wolff-Parkinson-White) syndrome, and other conduction abnormalities on

the ECG; (2) patients who have more than 1 mm of ST-segment depression at rest, including those with LV hypertrophy or taking drugs such as digitalis; and (3) patients who are unable to exercise to a level high enough to give meaningful results on the exercise ECG. Stress imaging is also reasonable in patients with CAD who have undergone previous revascularization, for whom localizing ischemia

TABLE 54G-1 ACCF/AHA Guidelines for Stress Testing and Advanced Imaging for Initial Diagnosis in Patients with Suspected Stable Ischemic Heart Disease Who Require Noninvasive Testing

TEST	EXERCISE STATUS		ECG INTERPRETABLE		PRETEST PROBABILITY OF ISCHEMIC HEART DISEASE			RECOMMENDATION	LEVEL OF EVIDENCE

CAC = coronary artery calcium (imaging); CCTA = coronary computed tomography angiography; CMR = cardiac magnetic resonance; ECG = electrocardiography; Echo = echocardiography; MPI = myocardial perfusion imaging.

and establishing the significance of lesions are important. It is reasonable also in patients with an intermediate to high pretest probability of obstructive CAD, even those with an interpretable ECG and moderate or better physical functioning (Table 54G-1).

The guidelines specify that exercise stress is preferable to pharmacologic stress when the patient can exercise to at least moderate physical functioning. Table 54G-1 summarizes the appropriate indications for stress imaging in patients who are and who are not able to exercise. As is the case with the exercise ECG, these tests are considered most useful for diagnosis in patients with an intermediate probability of disease.

Coronary Computed Tomography Angiography

The ACCF/AHA guidelines indicate that coronary computed tomography angiography (CCTA; see Chapter 18) is reasonable (class IIa) for patients with a low to intermediate pretest probability of CAD who are incapable of exercising or have persistent symptoms after other testing has provided normal or inconclusive results (Table 54G-1). CCTA may be reasonable (class IIb) for patients with an intermediate pretest probability of CAD who are capable of exercising.

Specific Patient Subsets

Although treadmill electrocardiographic testing is less accurate for diagnosis in women than in men, the guidelines note that the diagnostic performance of imaging technologies is also compromised by technical issues (e.g., breast tissue) in women. Therefore the guidelines conclude that “there currently are insufficient data to justify replacing standard exercise testing with stress imaging in the initial evaluation of women.”

Coronary Angiography

In the 2012 ACCF/AHA guidelines, invasive coronary angiography plays a very limited role in the diagnosis of CAD. The guidelines do support coronary angiography for diagnosis in patients with suspected SIHD who (1) have survived sudden death or serious ventricular arrhythmias or (2) have symptoms or findings that suggest high-risk coronary lesions (see Fig. 54G-1). The use of invasive coronary angiography for risk assessment and to enable coronary revascularization is discussed in the section that follows.

RISK STRATIFICATION

The ACCF/AHA guidelines emphasize the following four factors that predict survival for patients with CAD: (1) LV function, (2) anatomic extent and severity of coronary atherosclerosis, (3) presence of recent plaque rupture, and (4) the patient's general health and non-coronary comorbidity.

Assessment of Left Ventricular Function and Other Structural Heart Disease

The guidelines consider echocardiographic assessment of LV function and evaluation for myocardial, valvular, or pericardial abnormalities (class I) appropriate in patients with known or suspected IHD and symptoms or signs of heart failure, a history of previous MI, pathologic Q waves on the ECG, complex ventricular arrhythmias, or an undiagnosed heart murmur. Echocardiography may be considered (class IIb) for patients with hypertension or

diabetes mellitus and abnormal findings on an ECG. Use of radionuclide imaging to assess LV function may be considered in patients with previous MI provided that there is no need to evaluate because of heart failure, heart murmur, or arrhythmias. Routine use of echocardiography for patients with normal findings on an ECG, no history of MI, and no evidence of structural heart disease is considered inappropriate (class III).

Noninvasive Tests for Ischemia

Exercise testing is recommended for assessment of prognosis in all patients with known SIHD who are able to exercise, except those with an uninterpretable ECG (Table 54G-2). In such patients, use of nuclear myocardial perfusion imaging (MPI) or echocardiography is indicated. Pharmacologic stress imaging is discouraged in patients who are able to exercise.

Coronary Angiography

In the ACCF/AHA guidelines the decision to proceed to coronary angiography should be based on symptomatic status and risk stratification derived from clinical data and noninvasive test results. Coronary angiography is a necessary step for the management of patients

in whom coronary revascularization is likely to be beneficial because of a high risk for complications with medical therapy alone. Thus the guidelines support coronary angiography for diagnosis in patients with suspected SIHD who (1) have survived sudden death, (2) have signs or symptoms of heart failure, (3) have a high likelihood of severe IHD and the potential benefits are deemed to exceed the risk, or (4) have persistent symptoms despite an adequate trial of guideline-directed medical therapy (GDMT) (Table 54G-3; see also Fig. 54G-3). Coronary angiography is possibly indicated (class IIa) when (1) patients with known or suspected SIHD have a reduced ejection fraction along with demonstrable ischemia and moderate-risk criteria on noninvasive testing, (2) there are contraindications to noninvasive testing, or (3) such testing is inadequate to guide management.

The ACCF/AHA guidelines conclude that there is no benefit of coronary angiography in patients who are at low risk according to clinical criteria and have not undergone or have no evidence of ischemia on noninvasive testing.

TREATMENT

The ACCF/AHA guidelines for medical therapy in patients with SIHD are oriented toward preventing death while maximizing health and

TABLE 54G-3 ACCF/AHA Guidelines for Coronary Angiography to Assess Risk in Patients with Known or Suspected Stable Ischemic Heart Disease

CLASS	INDICATION	LEVEL OF EVIDENCE
I (indicated)	1. Patients with SIHD who have survived sudden cardiac death or potentially life-threatening ventricular arrhythmia should undergo coronary angiography to assess cardiac risk.	B
	2. Patients with SIHD in whom symptoms and signs of heart failure develop should be evaluated to determine whether coronary angiography should be performed for risk assessment.	B
	3. Coronary arteriography is recommended for patients with SIHD whose clinical characteristics and results of noninvasive testing indicate a high likelihood of severe IHD and when the benefits are deemed to exceed risk.	C
IIa (good supportive evidence)	1. Coronary angiography is reasonable to further assess risk in patients with SIHD who have depressed LV function (EF < 50%) and moderate-risk criteria on noninvasive testing with demonstrable ischemia.	C
	2. Coronary angiography is reasonable to further assess risk in patients with SIHD and inconclusive prognostic information after noninvasive testing or in patients for whom noninvasive testing is contraindicated or inadequate.	C
	3. Coronary angiography for risk assessment is reasonable for patients with SIHD who have unsatisfactory quality of life because of angina, have preserved LV function (EF > 50%), and have intermediate-risk criteria on noninvasive testing.	C
III (no benefit)	1. Coronary angiography for risk assessment is not recommended in patients with SIHD who elect not to undergo revascularization or who are not candidates for revascularization because of comorbid conditions or individual preferences.	B
	2. Coronary angiography is not recommended to further assess risk in patients with SIHD who have preserved LV function (EF > 50%) and low-risk criteria on noninvasive testing.	B
	3. Coronary angiography is not recommended to assess risk in patients who are at low risk according to clinical criteria and who have not undergone noninvasive risk testing.	C
	4. Coronary angiography is not recommended to assess risk in asymptomatic patients with no evidence of ischemia on noninvasive testing.	C

EF = ejection fraction.

TABLE 54G-4 ACCF/AHA Goals for Management of Stable Ischemic Heart Disease

1. Reduce premature cardiovascular death.
2. Prevent complications of SIHD that directly or indirectly impair patients' functional well-being, including nonfatal acute MI and heart failure.
3. Maintain or restore a level of activity, functional capacity, and quality of life that is satisfactory to the patient.
4. Completely or almost completely eliminate ischemic symptoms.
5. Minimize the cost of health care, in particular by eliminating avoidable adverse effects of tests and treatments and by preventing hospital admissions.

function. More specific objectives are shown in [Table 54G-4](#). Coronary revascularization is recommended when it has been shown to extend life, but in many settings there are a variety of reasonable options, including GDMT, percutaneous coronary intervention (PCI) ([see Chapter 55](#)), and coronary artery bypass grafting (CABG) ([Fig. 54G-3](#)). Cost-effectiveness and patient preference are considered important components in decision making.

The guidelines identify five complementary strategies: (1) educate patients about the cause, manifestations, and treatment options for IHD; (2) identify and treat conditions that contribute to, worsen, or complicate IHD; (3) modify risk factors for IHD (see below); (4) use evidence-based pharmacologic treatments to improve health status and survival; and (5) use coronary revascularization when there is clear evidence of the potential to improve health status and survival.

Risk Factor Modification

The ACCF/AHA guidelines support lifestyle modifications, including daily physical activity and weight management, for all patients with

SIHD ([Table 54G-5](#)) and also recommend intensive management of risk factors, including hypertension (target blood pressure <140/90 mm Hg), cigarette smoking, diabetes, low-density lipoprotein (LDL) cholesterol, and obesity ([Table 54G-6](#); see also [Table 54G-5](#)). The guidelines support dietary therapy for all patients and a moderate or high dose of a statin in the absence of contraindications or documented adverse effects. Other goals for risk reduction are summarized in [Table 54G-5](#).

Pharmacologic Therapy

The guidelines emphasize the importance of aspirin for patients with SIHD in the absence of contraindications ([Table 54G-7](#)). In the absence of contraindications, beta-blocking agents are recommended for 3 years in all patients after an acute coronary syndrome who have normal LV function and indefinitely in all patients with SIHD and LV systolic dysfunction. The evidence for beta blockers as chronic therapy in other patients with SIHD is weaker (class IIb, level of evidence C). Absolute contraindications to beta blockers include severe bradycardia, preexisting high degree of atrioventricular block, sick sinus syndrome, and severe unstable LV failure; relative contraindications include asthma and bronchospastic disease, severe depression, and peripheral vascular disease.

Angiotensin-converting enzyme (ACE) inhibitors are recommended (class I, [Table 54G-7](#)) for patients with SIHD who also have diabetes, hypertension, chronic kidney disease, and/or LV systolic dysfunction and may be considered in other patients with CAD (class IIa).

The guidelines recommend beta-blocking agents as initial therapy for relief of symptoms of myocardial ischemia in patients with SIHD ([Table 54G-8](#)). Long-acting nitrates and/or calcium antagonists (class I) or ranolazine (class IIa) should be used (or added) for symptom control when beta blockers are contraindicated, not tolerated, or ineffective. Annual influenza vaccination is recommended for patients with SIHD.

TABLE 54G-5 ACCF/AHA Guidelines for Risk Factor Modification

CLASS	INDICATION	LEVEL OF EVIDENCE
Lipid Management		
I (indicated)	1. Lifestyle modifications, including daily physical activity and weight management, are strongly recommended for all patients with SIHD.	B
	2. Dietary therapy for all patients should include reduced intake of saturated fats (to <7% of total calories), trans fatty acids (to <1% of total calories), and cholesterol (to <200 mg/day).	B
	3. In addition to therapeutic lifestyle changes, a moderate or high dose of a statin should be prescribed in the absence of contraindications or documented adverse effects.	A
IIa (good supportive evidence)	For patients who do not tolerate statins, LDL cholesterol-lowering therapy with bile acid sequestrants, niacin, or both is reasonable.	B
Blood Pressure Management		
I (indicated)	1. All patients should be counseled about the need for lifestyle modification: weight control; increased physical activity; alcohol moderation; sodium reduction; and emphasis on increased consumption of fresh fruits, vegetables, and low-fat dairy products.	B
	2. In patients with SIHD and a BP of 140/90 mm Hg or higher, antihypertensive drug therapy should be instituted in addition to or after a trial of lifestyle modifications.	A
	3. The specific medications used for the treatment of high BP should be based on specific patient characteristics and may include ACE inhibitors and/or beta-blocking agents, as well as the addition of other drugs such as thiazide diuretics or calcium channel blocking agents if needed to achieve a goal BP of less than 140/90 mm Hg.	B
Diabetes Management		
IIa (good supportive evidence)	1. For selected individual patients, such as those with a short duration of diabetes mellitus and a long life expectancy, a goal hemoglobin A1c (HbA1c) of 7% or less is reasonable.	B
	2. A goal HbA1c between 7% and 9% is reasonable for certain patients according to age, history of hypoglycemia, presence of microvascular or macrovascular complications, or presence of coexisting medical conditions.	C
IIb (weak supportive evidence)	Initiation of pharmacotherapy interventions to achieve a target HbA1c might be reasonable.	A
III (not indicated)	Therapy with rosiglitazone should not be initiated in patients with SIHD.	C
Physical Activity		
I (indicated)	1. For all patients, clinicians should encourage 30 to 60 minutes of moderate-intensity aerobic activity at least 5 days and preferably 7 days per week, supplemented by an increase in daily lifestyle activities (e.g., walking breaks at work, gardening, household work) to improve cardiorespiratory fitness and move patients out of the least-fit, least-active, high-risk cohort (bottom 20%).	B
	2. For all patients, risk assessment with a physical activity history and/or an exercise test is recommended to guide prognosis and prescription.	B
	3. Medically supervised programs (cardiac rehabilitation) and physician-directed, home-based programs are recommended for at-risk patients at first diagnosis.	A
IIa (good supportive evidence)	It is reasonable for clinicians to recommend complementary resistance training at least 2 days per week.	C
Weight Management		
I (indicated)	1. BMI and/or waist circumference should be assessed at every visit, and clinicians should consistently encourage weight maintenance or reduction through an appropriate balance of lifestyle physical activity, structured exercise, caloric intake, and formal behavioral programs when indicated to maintain or achieve a BMI of between 18.5 and 24.9 kg/m ² and a waist circumference of less than 102 cm (40 inches) in men and less than 88 cm (35 inches) in women (less for certain racial groups)	B
	2. The initial goal of weight loss therapy should be to reduce body weight by approximately 5% to 10% from baseline. With success, further weight loss can be attempted if indicated.	C
Smoking Cessation		
I (indicated)	Smoking cessation and avoidance of exposure to environmental tobacco smoke at work and home should be encouraged for all patients with SIHD. Follow-up, referral to special programs, and pharmacotherapy are recommended, as is a stepwise strategy for smoking cessation (Ask, Advise, Assess, Assist, Arrange, Avoid).	B

TABLE 54G-5 ACCF/AHA Guidelines for Risk Factor Modification—cont'd

CLASS	INDICATION	LEVEL OF EVIDENCE
Management of Psychological Factors		
Ila (good supportive evidence)	It is reasonable to consider screening patients with SIHD for depression and to refer or treat when indicated.	B
IIb (weak supportive evidence)	Treatment of depression has not been shown to improve cardiovascular disease outcomes but might be reasonable for its other clinical benefits.	C
Alcohol Consumption		
IIb (weak supportive evidence)	In patients with SIHD who drink alcohol, it might be reasonable for nonpregnant women to have 1 drink (4 oz of wine, 12 oz of beer, or 1 oz of spirits) a day and for men to have 1 or 2 drinks a day unless alcohol is contraindicated (such as in patients with a history of alcohol abuse or dependence or those with liver disease).	C
Exposure to Air Pollution		
Ila (good supportive evidence)	It is reasonable for patients with SIHD to avoid exposure to increased air pollution to reduce their risk for cardiovascular events.	C

BMI = body mass index.

TABLE 54G-6 Indications for Individual Drug Classes in the Treatment of Hypertension in Patients with Stable Ischemic Heart Disease

INDICATION	DIURETIC	BETA-BLOCKING AGENT	ACE INHIBITOR	ARB	CALCIUM-CHANNEL BLOCKER	ALDOSTERONE ANTAGONIST
Heart failure	X	X	X	X		X
LV dysfunction			X	X		
Post-MI status		X	X	X		X
Angina		X			X	
Diabetes mellitus		X	X	X		
CKD			X	X		

This table indicates drugs that should be considered and does not indicate that all drugs should necessarily be prescribed in an individual patient (e.g., ACE inhibitors and ARBs are not typically prescribed together).

ACE = angiotensin-converting enzyme; ARB = angiotensin receptor blocking agent; CKD = chronic kidney disease.

TABLE 54G-7 ACCF/AHA Guidelines for Medical Therapy to Prevent Myocardial Infarction and Death

CLASS	INDICATION	LEVEL OF EVIDENCE
Antiplatelet Therapy		
I (indicated)	1. Treatment with aspirin, 75 to 162 mg daily, should be continued indefinitely in the absence of contraindications in patients with SIHD.	A
	2. Treatment with clopidogrel is reasonable when aspirin is contraindicated in patients with SIHD.	B
IIb (weak supportive evidence)	3. Treatment with aspirin, 75 to 162 mg daily, and clopidogrel, 75 mg daily, might be reasonable in certain high-risk patients with SIHD.	B
III (no benefit)	Dipyridamole is not recommended as antiplatelet therapy for patients with SIHD.	B
Beta-Blocking Therapy		
I (indicated)	1. Beta-blocking therapy should be started and continued for 3 years in all patients with normal LV function after MI or ACS.	B
	2. Beta-blocking therapy should be used in all patients with LV systolic dysfunction (EF <40%) and heart failure or previous MI unless contraindicated. (Use should be limited to carvedilol, metoprolol succinate, or bisoprolol, which have been shown to reduce the risk for death.)	A
IIb (weak supportive evidence)	Beta-blocking agents may be considered as chronic therapy for all other patients with coronary or other vascular disease.	C
Renin-Angiotensin-Aldosterone Blocker Therapy		
I (Indicated)	ACE inhibitors should be prescribed in all patients with SIHD who also have hypertension, diabetes mellitus, LVEF of 40% or less, or CKD unless contraindicated.	A
	ARBs are recommended for patients with SIHD who have hypertension, diabetes mellitus, LV systolic dysfunction, or CKD and have indications for but are intolerant of ACE inhibitors.	A
IIa (good supportive evidence)	1. Treatment with an ACE inhibitor is reasonable in patients with both SIHD and other vascular disease.	B
	2. It is reasonable to use ARBs in other patients who are intolerant of ACE inhibitors.	C

Continued

TABLE 54G-7 ACCF/AHA Guidelines for Medical Therapy to Prevent Myocardial Infarction and Death—cont'd

CLASS	INDICATION	LEVEL OF EVIDENCE
Other Therapies		
III (not indicated)	1. Estrogen therapy is not recommended in postmenopausal women with SIHD with the intent of reducing cardiovascular risk or improving clinical outcomes.	A
	2. Vitamin C, vitamin E, and beta-carotene supplementation is not recommended with the intent of reducing cardiovascular risk or improving clinical outcomes in patients with SIHD.	A
	3. Treatment of elevated homocysteine with folate or vitamins B ₆ and B ₁₂ is not recommended with the intent of reducing cardiovascular risk or improving clinical outcomes in patients with SIHD.	A
	4. Chelation therapy is not recommended with the intent of improving symptoms or reducing cardiovascular risk in patients with SIHD.	C
	5. Treatment with garlic, coenzyme Q ₁₀ , selenium, or chromium is not recommended with the intent of reducing cardiovascular risk or improving clinical outcomes in patients with SIHD.	C

ACS = acute coronary syndrome; ARB = angiotensin receptor blocker; CKD = chronic kidney disease; EF = ejection fraction.

TABLE 54G-8 ACCF/AHA Guidelines for Medical Therapy for Relief of Symptoms

CLASS	INDICATION	LEVEL OF EVIDENCE
I (indicated)	1. Beta-blocking agents should be prescribed as initial therapy for relief of symptoms in patients with SIHD.	B
	2. Calcium channel blocking agents* or long-acting nitrates should be prescribed for relief of symptoms when beta-blocking agents are contraindicated or cause unacceptable side effects in patients with SIHD.	B
	3. Calcium channel blocking agents* or long-acting nitrates, in combination with beta-blocking agents, should be prescribed for relief of symptoms when initial treatment with beta-blocking agents is unsuccessful in patients with SIHD.	B
	4. Sublingual nitroglycerin or nitroglycerin spray is recommended for immediate relief of angina in patients with SIHD.	B
IIa (good supportive evidence)	1. Treatment with a long-acting nondihydropyridine calcium channel blocker (verapamil or diltiazem) instead of a beta-blocking agent as initial therapy for relief of symptoms is reasonable in patients with SIHD.	B
	2. Ranolazine can be useful when prescribed as a substitute for a beta-blocking agent for relief of symptoms in patients with SIHD if initial treatment with beta-blocking agents leads to unacceptable side effects or is ineffective or if initial treatment with beta-blocking agents is contraindicated.	B
	3. Ranolazine in combination with beta-blocking agents can be useful when prescribed for relief of symptoms when initial treatment with beta-blocking agents is not successful in patients with SIHD.	A
IIb (weak supportive evidence)	1. Enhanced external counterpulsation may be considered for relief of refractory angina in patients with SIHD.	B
	2. Spinal cord stimulation may be considered for relief of refractory angina in patients with SIHD.	C
	3. Transmyocardial revascularization may be considered for relief of refractory angina in patients with SIHD.	B
III (not indicated)	Acupuncture should not be used for the purpose of improving symptoms or reducing cardiovascular risk in patients with SIHD.	C

*Short-acting dihydropyridine calcium antagonists should be avoided.

Revascularization

The ACCF/AHA guidelines for revascularization focus on improvement of survival (Fig. 54G-4 and Table 54G-9) in patients with SIHD and high clinical risk for mortality with GDMT and in those who have inadequate control of symptoms and quality of life despite GDMT (Table 54G-10; see also Fig. 54G-4). Recommendations include CABG for patients with significant left main CAD, triple-vessel CAD, or proximal left anterior descending (LAD) disease plus one other major coronary artery. CABG is reasonable (class IIa) for patients with double-vessel CAD who have evidence of severe or extensive myocardial ischemia or mild to moderate LV systolic dysfunction with viable myocardium in the region of intended revascularization. CABG is given preference over PCI (class IIa) in patients with complex three-vessel disease and those with diabetes mellitus.

The guidelines discourage the use of PCI or CABG for single- or double-vessel CAD without significant involvement of the proximal LAD artery in the absence of unacceptable angina after an adequate trial of GDMT, particularly if noninvasive testing data indicate that

they have only a small area of viable myocardium or do not have extensive ischemia or reduced LV ejection fraction (Tables 54G-9 and 54G-10).

Alternative Therapies

The guidelines do not consider alternative therapies to be sufficiently supported by evidence to warrant a class I indication for patients with SIHD (see Tables 54G-6 and 54G-8). Surgical laser transmyocardial revascularization, enhanced external counterpulsation, and spinal cord stimulation are given class IIb indications.

PATIENT FOLLOW-UP

The ACCF/AHA guidelines recommend that patients with SIHD have follow-up evaluations at least annually for assessment of symptoms and clinical function, surveillance of complications of SIHD, monitoring of cardiac risk factors, and assessment of the adequacy of and adherence to lifestyle interventions and GDMT (Table 54G-11).

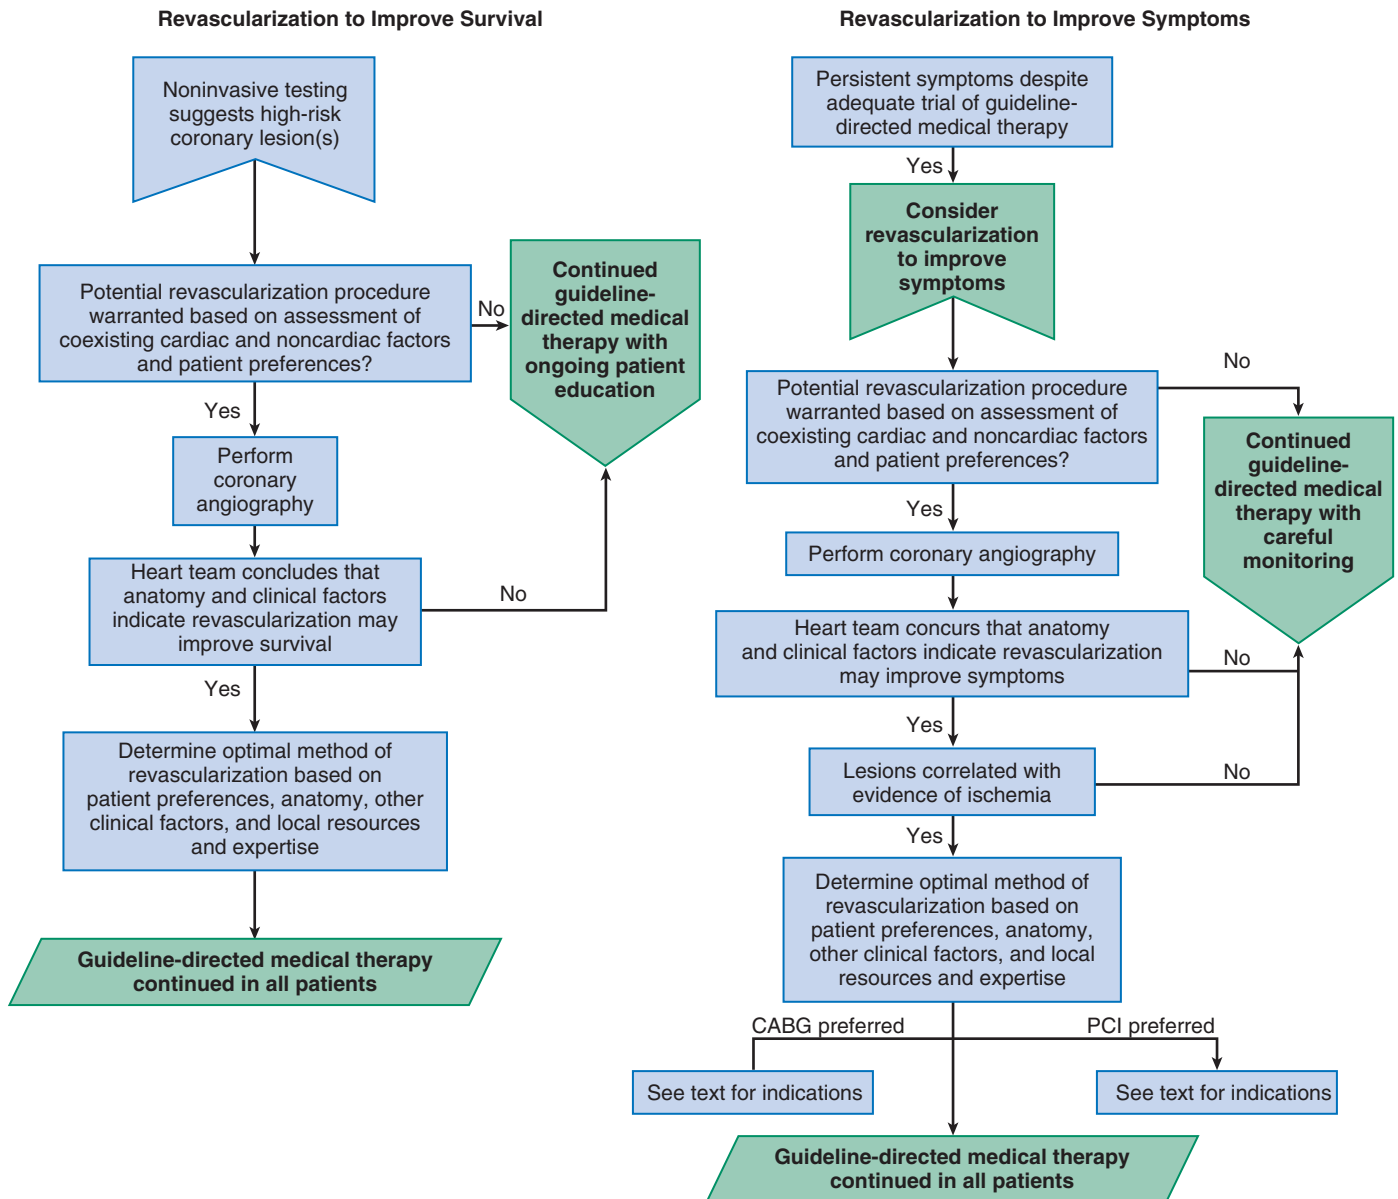

FIGURE 54G-4 Algorithm for revascularization to improve survival (left) and symptoms (right) in patients with SIHD. The algorithms do not represent a comprehensive list of recommendations (see full guideline text for all recommendations). (From Fihn SD, Gardin JM, Abrams J, et al: 2012 ACCF/AHA/ACP/AATS/PCNA/SCAI/STS guideline for the diagnosis and management of patients with stable ischemic heart disease: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, and the American College of Physicians, American Association for Thoracic Surgery, Preventive Cardiovascular Nurses Association, Society for Cardiovascular Angiography and Interventions, and Society of Thoracic Surgeons. *J Am Coll Cardiol* 60:2564, 2012.)

TABLE 54G-9 ACCF/AHA Guidelines for Revascularization to Improve Survival versus Medical Therapy in Patients with Stable Ischemic Heart Disease

ANATOMIC SETTING	CLASS	RECOMMENDATION	LEVEL OF EVIDENCE
Unprotected Left Main or Complex Coronary Artery Disease			
CABG and PCI	I	Heart team approach	C
CABG and PCI	IIa	Calculation of STS and SYNTAX Scores	B
Unprotected Left Main			
CABG	I		B
PCI	IIa	For SIHD when both of the following are present: 1. Anatomic conditions associated with a low risk for PCI procedural complications and a high likelihood of a good long-term outcome 2. Clinical characteristics that predict a significantly increased risk for adverse surgical outcomes	B
	IIb	For SIHD when both of the following are present: 1. Anatomic conditions associated with a low to intermediate risk for PCI procedural complications and an intermediate to high likelihood of a good long-term outcome 2. Clinical characteristics that predict increased risk for adverse surgical outcomes (e.g. STS-predicted operative mortality >2%)	B
	III	For SIHD in patients (versus performing CABG) with unfavorable anatomy for PCI and who are good candidates for CABG	B
Three-Vessel Coronary Artery Disease with or without Proximal Left Anterior Descending Coronary Artery Disease			
CABG	I		B
	IIa	It is reasonable to choose CABG over PCI in patients with complex 3-vessel CAD (e.g., SYNTAX score ≥ 22) who are good candidates for CABG	B
PCI	IIb		B
Two-Vessel Coronary Artery Disease with Proximal Left Anterior Descending Coronary Artery Disease			
CABG	I		B

Exercise ECG at ≥1-year intervals	X		X		Previous silent ischemia or at high risk for recurrent event		IIb	C
Exercise ECG	X		X		No previous silent ischemia and not at high risk for recurrent events		IIb	C
Exercise or pharmacologic stress imaging or CCTA	Either		Either			<5-yr intervals after CABG or <2 yr intervals after PCI	III	C

ECG = electrocardiography; CMR = cardiac magnetic resonance; Echo = echocardiography.

Assessment of the LV ejection fraction is recommended for patients with SIHD and new or worsening heart failure or evidence of intervening MI. The guidelines urge restraint in the use of routine testing in the follow-up of patients with SIHD if they have not had a change in clinical status (**Table 54G-12**). All the class I indications for testing are for patients who have had a significant change in clinical status, except for coronary angiography in patients with marked limitations in ordinary activity despite optimal GDMT.

The use of percutaneous coronary intervention (PCI) to treat ischemic coronary artery disease (CAD) has expanded dramatically over the past three decades. In the absence of left main or complex multivessel CAD, PCI is the preferred method of revascularization in the United States for most patients with ischemic CAD. The estimated 600,000 PCI procedures performed annually in the United States exceed the number of coronary artery bypass graft (CABG) procedures.¹ Over the past several years, however, the growth of PCI has slowed because of the effectiveness of risk factor modification, prevention of restenosis with drug-eluting stents (DESs), and a better understanding of the patients who will benefit from revascularization.^{2,3} The number of PCIs is expected to grow modestly (1% to 5%) over the next decade as a result of the aging U.S. population and an increased frequency of obesity and diabetes. Other key enablers of the expanded use of PCI in patients with complex CAD include improvements in equipment design (e.g., catheters with lower profile and enhanced deliverability), the development of adjunctive pharmacologic strategies (e.g., adenosine diphosphate [ADP] receptor antagonists and direct thrombin inhibitors) to improve safety, and better hemodynamic support devices in “ultrahigh”-risk patients. “Hybrid” procedures for the treatment of CAD and valvular heart disease have also been performed with the collaboration of interventional cardiologists and cardiac surgeons.^{4,5}

This chapter reviews the indications and clinical considerations for the selection of patients for PCI; discusses the current array of coronary devices, antithrombotic therapy, vascular access approaches, and vascular closure devices used for PCI; details the short- and long-term outcomes of PCI; and summarizes the requirements for operator and institutional proficiency.

Coronary balloon angioplasty, or percutaneous transluminal coronary angioplasty (PTCA), was first performed by Andreas Gruentzig in 1977 with a fixed-wire balloon catheter. The procedure was initially limited to the fewer than 10% of patients with symptomatic CAD who had a single, focal, noncalcified lesion in a proximal coronary vessel. As equipment design and operator experience evolved over the next decade, the use of PCI expanded to encompass an increasing spectrum of coronary anatomy—including multivessel CAD, total occlusions, diseased saphenous vein grafts (SVGs), and acute ST-segment elevation myocardial infarction (STEMI) (see Chapter 52), among other complexities. Two limitations prevented the widespread use of balloon angioplasty for CAD: abrupt closure of the treated vessel occurred in 5% to 8% of cases and required emergency CABG in 3% to 5%, and restenosis resulted in recurrence of symptoms in 30% of patients within the following year.

New coronary devices were developed in the late 1980s to overcome the limitations associated with balloon angioplasty. Coronary stents act as a scaffold on the inner arterial wall to prevent early and

late vascular remodeling. Rotational atherectomy ablates calcific atherosclerotic plaque and was developed as stand-alone therapy for nondilatable coronary stenoses or for use in combination with coronary stents following the ablation of calcific plaque. By the early 2000s, several devices had been developed to protect the distal circulation from atherothrombotic embolization (i.e., embolic protection devices). Aspiration and thrombectomy catheters were developed to remove medium and large thrombi from within the coronary artery, thereby preventing distal embolization. The term *percutaneous coronary intervention* now encompasses the broad array of balloons, stents, and adjunctive devices required to perform safe and effective percutaneous revascularization in complex coronary artery lesions.

INDICATIONS FOR PERCUTANEOUS CORONARY INTERVENTION

Clinical Presentations

The major value of percutaneous or surgical coronary revascularization is relief of the symptoms and signs of ischemic CAD (see Chapters 52 and 54 and PCI Guidelines at the end of this chapter). PCI reduces the risk for mortality and subsequent myocardial infarction (MI) when compared with medical therapy in patients with acute coronary syndromes. Optimal medical therapy appears to be as effective as PCI in reducing death and MI in patients with stable angina, although relief of symptoms² and improvement of ischemia⁶ are better with PCI. Greater than 5% improvement in the ischemic burden is achieved more often with PCI, and the magnitude of the residual ischemia correlates with less frequent death and MI.⁶ Further studies comparing the use of coronary arteriography and PCI in patients with moderate degrees of myocardial ischemia are planned (e.g., ISCHEMIA [International Study of Comparative Health Effectiveness with Medical and Invasive Approaches]),⁷ and recent randomized trials requiring physiologic evidence of ischemia (as measured by fractional flow reserve [FFR]) have identified a benefit of PCI over medical therapy in preventing urgent revascularization.⁸ Irrespective of the indication for revascularization, PCI should be coupled with optimal medical therapy after the procedure, such as control of hypertension and diabetes, exercise, and smoking cessation (see Chapter 42 and PCI Guidelines in this chapter). Lipid management, particularly statin use, is also an important component of optimal medical therapy.

When compared with PCI alone, CABG is associated with a late mortality benefit in certain high-risk medical and anatomic subsets, such as patients with left main disease, three-vessel CAD, and extensive markers of higher anatomic risk for PCI (as determined by a SYNTAX [Synergy Between PCI with TAXUS and Cardiac

Surgery] score, for example)⁹ or patients with diabetes and significant multivessel disease.¹⁰ These benefits are manifested beyond 1 year after treatment and for up to 5 years of follow-up, but the early periprocedural risks, particularly for stroke, are higher with CABG, and it has a longer in-hospital recovery period. The risks and benefits associated with coronary revascularization therefore need careful review with the patient and family, and the relative options of PCI, CABG, or optimal medical therapy should be discussed before performing these procedures. Patients with multivessel disease benefit from joint consultation with a cardiac surgeon, an interventional cardiologist, and the referring cardiologist, and consideration of patient preferences in weighing diverse factors is valuable. A task force of the American College of Cardiology (ACC) and American Heart Association (AHA) has published guidelines for the performance of PCI and CABG procedures,¹¹⁻¹³ and a multispecialty writing committee has developed appropriate use criteria for revascularization in several clinical and lesion-specific subsets (see [PCI Guidelines](#)).^{14,15}

Asymptomatic or Minimally Symptomatic Patients

Asymptomatic patients or those who have only mild symptoms are generally best treated with medical therapy unless one or more high-grade lesions subtend a moderate to large area of viable myocardium, the patient prefers to maintain a very active lifestyle or has a high-risk occupation, and the procedure can be performed with a high chance of success and low likelihood of complications (see [PCI Guidelines](#) at the end of this chapter).¹⁵ Patients who are minimally symptomatic or asymptomatic should not undergo coronary revascularization if only a small area of myocardium is at risk, if no objective evidence of ischemia can be detected, or if the likelihood of success is low or the chance of complications is high.¹⁴

Patients with Moderate to Severe Angina (See Chapter 54)

Patients with Canadian Cardiovascular Society (CCS) class III angina, particularly those who are refractory to medical therapy, can benefit from coronary revascularization, provided that the lesion subtends a moderate to large area of viable myocardium as determined by non-invasive testing.¹² Patients with recurrent symptoms while receiving medical therapy are candidates for revascularization even if they have a higher risk for an adverse outcome with revascularization. Patients with class III symptoms should not undergo revascularization without noninvasive evidence of myocardial ischemia or a trial of medical therapy, particularly if only a small region of myocardium is at risk, the likelihood of success is low, or the chance of complications is high.¹⁴

Patients with Unstable Angina, Non-ST-Segment Elevation Myocardial Infarction, and ST-Segment Elevation Myocardial Infarction (see Chapters 52 and 53)

Cardiac catheterization and coronary revascularization in moderate- to high-risk patients with unstable angina or non-ST-segment elevation MI (NSTEMI) may improve mortality and reduce the rate of reinfarction.¹⁶ In a meta-analysis of seven trials with 8375 patients monitored for up to 2 years, the all-cause mortality rate was 4.9% in the early invasive group as compared with 6.5% in the conservative group (risk ratio [RR], 0.75; $P = 0.001$). The 2-year incidence of nonfatal MI was 7.6% in the invasive group and 9.1% in the conservative group (RR, 0.83; $P = 0.012$). At a mean of 13 months of follow-up, rehospitalization for unstable angina was reduced as well (RR, 0.69; $P < 0.0001$). Current guidelines suggest that an early invasive strategy should be pursued in patients with recurrent ischemia despite therapy, elevated troponin levels, new ST-segment depression, new or worsening symptoms of heart failure, depressed left ventricular (LV) function, hemodynamic instability, sustained ventricular tachycardia, or a recent PCI or CABG procedure (see [PCI Guidelines](#)).¹⁶

Several clinical recommendations pertaining to patients with STEMI, including primary PCI, rescue PCI, facilitated PCI, and PCI following successful thrombolysis, have been published (see [PCI](#)

[Guidelines](#)).¹⁷ Timely PCI in patients with STEMI improves survival over that achieved with medical therapy, provided that it is performed by a physician who routinely performs PCI, and that the hospital has sufficient PCI volume to support its proficiency. Patients with cardiogenic shock or severe heart failure also benefit from primary PCI, irrespective of their age at initial evaluation.

Left Main and Three-Vessel Coronary Artery Disease

The SYNTAX trial randomly assigned 1800 patients with multivessel or left main disease (1709 had multivessel disease) to PCI with a DES versus CABG.³ Complete revascularization was the goal for both study groups, and the average number of treated vessels and stents in patients undergoing PCI for left main or multivessel disease was 3.6 lesions and 4.6 stents. One-year outcomes were not different between the PCI and CABG groups in terms of all-cause mortality or MI. However, rates of major adverse cardiovascular or cerebrovascular events were significantly higher with PCI, mainly attributable to the significantly higher rates of target lesion revascularization in the PCI group. Three-year outcomes were similar to these findings, with no significant difference in all-cause mortality, but a persistently elevated rate of target lesion revascularization was associated with PCI.⁹ These findings were dependent on the SYNTAX score—an angiographic grading system to quantify the complexity of PCI (see [Chapter 20](#)). With low scores (≤ 22), there was no significant difference in the primary outcome between patients treated with PCI and those who underwent CABG, but with high scores (> 33), mortality and major adverse cardiovascular or cerebrovascular event rates were lower with CABG procedures.

Patients with Diabetes Mellitus

The largest trial to date devoted to studying outcomes after revascularization in patients with diabetes mellitus and multivessel disease is FREEDOM (Future Revascularization Evaluation in Patients with Diabetes Mellitus: Optimal Management of Multivessel Disease), a randomized controlled trial that compared the outcomes of PCI and CABG in patients with diabetes and multivessel disease.¹⁰ In this trial, diabetic patients requiring revascularization with angiographically proven multivessel disease and lesions amenable to either PCI or CABG were randomly assigned to complete coronary revascularization with one of these techniques. The primary outcome (all-cause mortality, nonfatal MI, or nonfatal stroke) at 5 years was better in patients treated with PCI than in those who underwent CABG (26.6% versus 18.7%, $P = 0.005$). Considering individual components of the primary outcome, there was a significantly increased long-term risk for all-cause mortality and nonfatal MI with PCI as opposed to CABG. CABG, however, was associated with an increased risk for nonfatal stroke, and the severity of strokes in the CABG group was twice as likely to severely disable a patient as were strokes occurring in the PCI group.

The results of the FREEDOM trial have largely validated smaller studies, subgroup analyses, and meta-analyses attempting to compare methods of revascularization in diabetic patients with multivessel disease. The CARDia (Coronary Artery Revascularization in Diabetes) randomized trial compared PCI with CABG; although smaller in size, it was dedicated to patients with diabetes, and a significant fraction suffered from multivessel disease.¹⁸ The trial lacked sufficient power to compare mortality. Like the FREEDOM trial, however, it revealed an increased risk for stroke in the CABG group. Similarly, even though most patients were treated with DESs in this trial, the need for repeated revascularization procedures was significantly increased with PCI.

Patients Without Options for Revascularization

Patients who suffer from substantial angina but are poor candidates for conventional revascularization have limited therapeutic options. These patients generally either have occlusion of a single proximal vessel that subtends a large amount of myocardium or have undergone one or more previous CABG operations with stenoses or occlusions of the SVGs, which are poorly suited for conventional repeated revascularization. “Limited-option” patients account for

approximately 4% to 12% of those undergoing coronary angiography; a larger group (20% to 30%) of patients has incomplete revascularization because the coronary anatomy is unsuitable for surgical or percutaneous techniques. Better techniques and equipment for crossing chronic total occlusions (see later) have helped some of these patients. Antianginal medications such as ranolazine (see Chapter 54) may also be particularly useful in this subset.

Patient-Specific Considerations for Percutaneous Coronary Intervention

Assessment of the potential risks and benefits of PCI must address five fundamental patient-specific risk factors: extent of jeopardized myocardium, baseline lesion morphology, underlying cardiac function (including LV function, rhythm stability, and coexisting valvular heart disease), presence of renal dysfunction, and preexisting medical comorbid conditions that may place the patient at higher risk for PCI. Each of these factors contributes independently to the risks and benefits attributable to PCI. Proper planning for a PCI procedure requires careful attention to each of these factors.

Extent of Jeopardized Myocardium

The proportion of viable myocardium subtended by the treated coronary artery is the principal consideration in assessing the acute risk associated with the PCI procedure. PCI interrupts coronary blood flow for a period of seconds to minutes, and the ability of patients to hemodynamically tolerate a sustained coronary occlusion depends on both the extent of “downstream” viable myocardium and the presence and grade of collaterals to the ischemic region. Although the risk for abrupt closure has been reduced substantially with the availability of coronary stents, when other procedural complications develop—such as a large side branch occlusion, distal embolization, perforation, or no-reflow—rapid clinical deterioration may occur that is proportionate to the extent of jeopardized myocardium. In the unlikely event that out-of-hospital stent thrombosis develops, the clinical sequelae of the episode are related to the extent of myocardium subtended by the occluded stent. Predictors of cardiovascular collapse with a failed PCI include the magnitude of myocardium at risk, the severity of the baseline stenosis, multivessel CAD, and the presence of diffuse disease.

Complete Versus Ischemia-Targeted Percutaneous Coronary Intervention for Multivessel Disease

The treatment approaches for PCI and CABG compared in randomized trials have essentially all focused on the strategy of complete revascularization. Data supporting complete revascularization of all angiographic lesions during treatment of multivessel disease with PCI or CABG have been observational (nonrandomized) and thus limited by selection bias in that patients in whom full revascularization is feasible are also those who are at lower risk for procedural and future adverse events. The concept of targeted treatment of vessels with only physiologically significant—not just angiographically significant—stenosis may be one that allows improved outcomes in patients with multivessel disease being treated with either PCI or CABG.

The FFR technique (see Chapters 49 and 54) involves placement of a pressure wire across a potentially significant lesion, and under conditions of maximal coronary blood flow, the ratio of pressure distal to versus proximal to a lesion or series of sequential lesions is measured within a given artery (Fig. 55-1). In contrast to traditional angiography, which can provide only an anatomic evaluation, FFR provides a functional assessment of the presence of a reduction in flow that correlates well with ischemia as detected by nuclear scintigraphy. The FAME (Fractional Flow Reserve versus Angiography for Multivessel Evaluation) trial compared angiography with FFR guidance for selection of lesions during DES PCI in more than 1000 patients.¹⁹ Only lesions with an FFR of 0.8 or less were considered to warrant PCI in the FFR arm. FFR guidance resulted in fewer overall stented lesions, and a 2-year analysis revealed significantly reduced mortality or MI with the use of FFR versus pure angiographic

FIGURE 55-1 Measurement of FFR. In red is the tracing of the pressure measured from the tip of the guide catheter. In green is the tracing measured from a wire-based pressure transducer placed distal to a coronary lesion. Measurements are taken during intravenous adenosine infusion. The FFR, noted in yellow, is the minimum value of the ratio of the mean instantaneous distal wire pressure to the mean instantaneous guide catheter pressure. A value of 0.80 or less was used in the FAME trial to determine whether FFR-guided angioplasty should be performed on a given lesion.¹⁹ (From St. Jude Medical, Minneapolis.)

guidance, thus corroborating not only the simple procedural benefit of FFR but also the morbidity and mortality advantages of stenting across physiologically relevant lesions.

In patients with STEMI, revascularization of only the culprit infarct-related artery is generally recommended¹⁴ unless there is ongoing cardiogenic shock because of jeopardized myocardium in other regions. Appropriately powered trials to determine whether nonculprit severe lesions should be treated even in the absence of shock are planned.

Baseline Lesion Morphology

Several angiographic findings increase the technical complexity of PCI and elevate the risk for acute and long-term complications. The initial ACC/AHA lesion classification system has been refined with use of the Society for Cardiovascular Angiography and Interventions (SCAI) risk system, which further characterizes risk by the presence or absence of total occlusion. Although coronary stents have reduced the need for emergency CABG from 3% to 8% with balloon angioplasty to less than 1% with the availability of coronary stents, they have not eliminated the risk for periprocedural MI, stent thrombosis, or distal embolization and “no reflow.” Vessel patency and lesion complexity remain important predictors of outcome in patients undergoing coronary stent placement. Reviews of registry data have confirmed the impact of high-risk lesion features on procedural success rates and the risk for short- and long-term complications. Most recently, the SYNTAX angiographic scoring system—when combined with clinical factors—has become a method of deciding between complex PCI and CABG.^{20,21} An online calculator is available (www.syntaxscore.com).

Chronic Total Occlusions

Chronic coronary occlusions occur in many patients with severe (>70% stenosis) CAD and are the most important factor leading to referral for CABG procedures rather than PCI. The inability of guidewires to recanalize total coronary occlusions is related to several factors, including the duration of the occlusion, the presence of bridging collaterals, occlusion length greater than 15 mm, and the absence of a “beak” to assist in advancement of the guidewire. Although approaches such as retrograde crossing via collaterals and newer

guidance technologies have been used to recanalize refractory occlusions, better guidewires and wire techniques have accounted for much of the improvement in successfully crossing occlusions over recent years.²² Once the chronic total occlusion has been crossed, DESs may be used to reduce late clinical recurrence.

Saphenous Vein Grafts

SVG interventions account for approximately 8% of PCI procedures and pose an increased risk for postprocedural MI as a result of the atheroembolization that occurs during PCI. When no-reflow occurs, administration of arterial vasodilators (e.g., nitroprusside, verapamil, or adenosine) into the SVG may improve flow into the distal native circulation, but the risk for death or MI is still substantially increased. More extensive SVG degeneration and bulkier lesions are associated with higher complication rates than are SVGs that have less extensive disease.²³ In the setting of “high-risk” SVG anatomy, alternative approaches using the native coronary artery should be pursued whenever possible. Lower rates of restenosis in SVG lesions occur after coronary stent placement than after balloon angioplasty. Although DESs provide lower restenosis rates in SVGs that are 4.0 mm or less, they are currently not available for SVGs larger than 4.5 mm in diameter, and bare metal stents (BMSs) are reasonable in this setting. Embolic protection devices are strongly recommended in patients treated for SVG stenoses to lessen the risk for distal embolization of atherothrombotic debris.

Bifurcation Lesions

Optimal management of lesions involving both branches of a coronary bifurcation remains controversial. “Snowplowing” of plaque into the adjacent parent vessel or side branch is a major limitation of conventional balloon angioplasty. Atheroablative procedures such as rotational atherectomy have not really reduced this risk. Risk stratification for bifurcation PCI includes assessment of the extent of atherosclerotic disease in both vessels, estimation of relative vessel size and distribution in the parent vessel and side branch, and determination of the orientation of the vessels to one another. Side branch compromise may also occur in up to 30% of bifurcation lesions without apparent branch vessel disease.

Stent placement in one vessel rather than in both the parent vessel and side branch is generally preferred. In a meta-analysis of six randomized trials that included 1642 patients with coronary bifurcation lesions who were randomly selected to undergo PCI involving either double or single stenting, the risk for MI increased with double stenting (RR, 1.78; $P = 0.001$).²⁴

When extensive disease occurs in both vessels, various strategies have been used, including simultaneous “kissing” stents (Fig. 55-2) and “crush,” culotte, T stenting, and TAP (“T and small protrusion”) techniques. Irrespective of the bifurcation stenting strategy used, a final kissing balloon inflation in the parent vessel and side branch should generally be performed. DESs appear to have lower restenosis rates than BMSs do, but when recurrence develops in patients treated with a DES, it generally occurs at the origin of the side branch. New dedicated

bifurcation stents and side branch access main vessel stents are in development. Determination of the FFR of an angiographically narrowed side branch can be useful if it demonstrates no significant impairment of flow and therefore no need to place a stent.

Lesion Calcification

The presence of extensive coronary calcification poses unique challenges for PCI because calcium in the vessel wall leads to irregular and inflexible lumens, thus making delivery of guidewires, balloons, and stents much more challenging. Extensive coronary calcification also renders the vessel wall rigid, which necessitates higher balloon inflation pressure to achieve complete stent expansion and, on occasion, leads to “undilatable” lesions that resist any balloon expansion pressure that can be achieved. Rotational atherectomy effectively ablates the vessel wall calcification and facilitates stent delivery and complete stent expansion (Fig. 55-3).

Thrombus

Conventional angiography has poor sensitivity for the detection of coronary thrombus, but the presence of a large, angiographically apparent coronary thrombus heightens the risk for procedural complications. Large coronary thrombi may fragment and embolize during PCI or may extrude through gaps between stent struts placed in the vessel, thereby risking lumen compromise or thrombus propagation and acute thrombosis of the treated vessel. In addition, large coronary thrombi can embolize to other coronary branches or vessels or dislodge and compromise the cerebral or other vascular beds. In the setting of STEMI, manual catheter aspiration of thrombus appears to reduce the risk for future ischemic events, including stent thrombosis and, potentially, mortality.

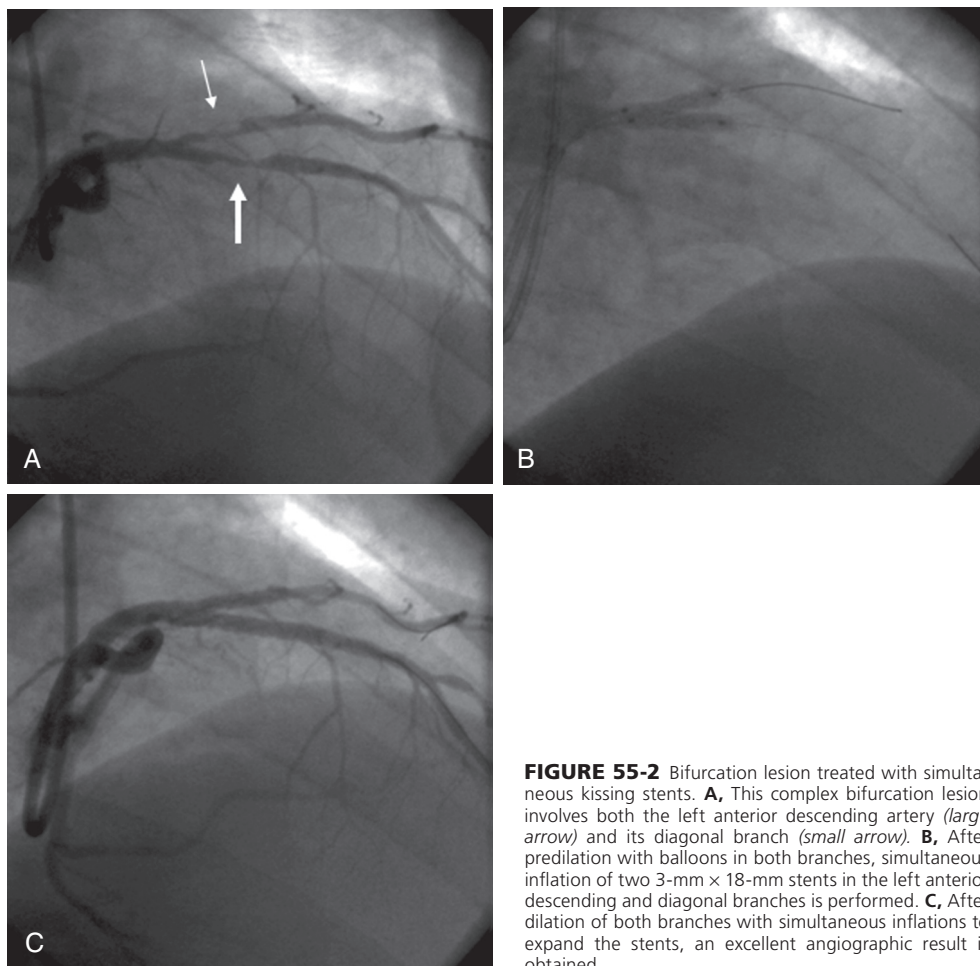

FIGURE 55-2 Bifurcation lesion treated with simultaneous kissing stents. **A**, This complex bifurcation lesion involves both the left anterior descending artery (large arrow) and its diagonal branch (small arrow). **B**, After predilation with balloons in both branches, simultaneous inflation of two 3-mm × 18-mm stents in the left anterior descending and diagonal branches is performed. **C**, After dilation of both branches with simultaneous inflations to expand the stents, an excellent angiographic result is obtained.

FIGURE 55-3 Rotational atherectomy of an ostial right coronary artery stenosis. **A**, A heavily calcified stenosis of the ostium of the right coronary artery (arrow) precludes conventional balloon angioplasty and stent placement. **B**, A 1.25-mm rotational atherectomy burr (arrow) was advanced to ablate the calcium in the ostium. An additional 1.5-mm rotational atherectomy burr was also used to further ablate the calcific plaque. **C**, After balloon predilation with a 2.5-mm balloon, a 3.5-mm × 23-mm stent was advanced and inflated to 16 atm. Note that the guiding catheter is withdrawn (arrow) to allow placement of the stent just at the origin of the right coronary artery. **D**, An excellent final angiographic result is obtained with no residual stenosis. Note the free reflux of contrast material from the right coronary artery ostium after stent placement (arrow).

Left Main Coronary Artery Disease

The presence of left main CAD has been an accepted indication for CABG because of the potential for hemodynamic collapse in the setting of acute complications, stent thrombosis, or restenosis involving the body of the left main coronary artery or its extension into the left anterior descending or left circumflex coronary artery. Registry and randomized studies have suggested that rates of death or MI are similar in patients undergoing CABG or PCI,^{3,25,26} although the need for repeated revascularization is higher in patients treated with PCI with additional vessel disease.^{3,27-34} The use of PCI for left main CAD has been elevated to a class IIb indication (see [PCI Guidelines](#) at the end of this chapter) pending additional ongoing randomized study, such as the EXCEL (Evaluation of Xience Prime versus Coronary Artery Bypass Surgery for Effectiveness of Left Main Revascularization) trial, in which patients with left main CAD lesions were randomly assigned to everolimus-eluting stents or CABG.

Underlying Cardiac Function

LV function is an important predictor of outcome during PCI. For each 10% decrement in resting LV ejection fraction, the risk for in-hospital mortality following PCI increases approximately twofold. Associated valvular disease or ventricular arrhythmia further increases the risk associated with PCI in the setting of LV dysfunction. Intra-aortic balloon pump support may be useful when LV function

is severely compromised (i.e., ejection fraction <35%) or when the PCI target lesion supplies a substantial portion of viable myocardium. Routine use of intra-aortic balloon pumps has limited benefit in patients with STEMI,³⁵ although they are recommended for patients in cardiogenic shock. Other percutaneous cardiopulmonary support devices that do not effectively reduce LV pressure have been replaced by percutaneous LV assist devices that are positioned in the left atrium (e.g., TandemHeart, CardiacAssist, Inc., Pittsburgh, Pa)^{36,37} or directly in the left ventricle (Impella, Abiomed, Inc., Danvers, Mass)³⁸⁻⁴⁰ ([Fig. 55-4](#)). These devices may permit very high-risk PCI with less chance of hemodynamic collapse during the procedure, although current data do not show them to be superior to intra-aortic balloon pumps.⁴¹ Peripheral extracorporeal membrane oxygenation (ECMO) support through large-bore arterial and venous access may be useful in cases of cardiovascular collapse.

Renal Insufficiency

The morbidity and mortality associated with PCI are directly related to the extent of baseline renal disease (see also [Chapter 88](#)). Patients with evidence of mild renal dysfunction have a 20% higher risk for death at 1 year following PCI than do those with preserved renal function. Renal dysfunction following the administration of contrast material during angiography may be related to contrast-induced nephropathy (see [Chapter 19](#)), to cholesterol embolization syndrome (see [Chapters 58 and 88](#)), or to both. The risk for nephropathy is

dependent on the dose of the contrast agents used, hydration status at the time of the procedure, preexisting renal function of the patient, age, hemodynamic stability, anemia, and diabetes. The risk for cholesterol embolization syndrome is related to manipulation of the catheter in an ascending or descending atherosclerotic aorta from which cholesterol crystals are released. Although the risk associated with hemodialysis is less than 3% in cases of uncomplicated contrast-induced nephropathy, in-hospital mortality in the setting of hemodialysis exceeds 30%. Mild renal dysfunction following PCI is associated with an up to fourfold increased risk for death at 1 year following PCI when compared with patients with preserved renal function, although this association is probably not causal.

Associated Medical Comorbid Conditions

A bleeding diathesis or need for chronic warfarin therapy may preclude patients from tolerating long-term combination aspirin and clopidogrel therapy after placement of a DES, thereby placing them at higher risk for stent thrombosis. The need for discontinuation of dual antiplatelet therapy before impending non-cardiac-related surgery soon after stent implantation may also predispose to stent thrombosis. In each of these circumstances, BMS placement may be the preferred approach, particularly if the surgery can be deferred for approximately 6 weeks after placement of the stent ([Fig. 55-5](#)).^{42,43}

VASCULAR ACCESS

The most frequently used vascular access sites for PCI include the common femoral artery, the brachial artery, and increasingly, the radial artery (see Chapters 19 and 20). The femoral approach (either right or left sided) is the most commonly used vascular access site in the United States and provides the advantages of large vessel size (typically 6 to 8 mm in diameter) and the ability to accommodate larger (>6 French [F]) sheath sizes, including intra-aortic balloon pumps. In addition, because of the typically straight path from the femoral artery to the ascending aorta, the femoral approach provides excellent guide catheter support and manipulability and access to the venous system through the adjacent femoral vein. The presence of severe peripheral arterial disease or peripheral vascular bypass grafts and the requirement for immobilization following the procedure limit use of the femoral approach in some patients.

The brachial arterial approach was historically used as the principal alternative to femoral access, but because the brachial artery

TABLE 55-1 Outcomes in Radial Versus Femoral Access in the RIVAL Trial

	FEMORAL (N = 3514)	RADIAL (N = 3507)	P VALUE
Composite of death, MI, stroke, or non-CABG-related major bleeding at 30 days*	4.0%	3.7%	0.50
Death at 30 days	1.5%	1.3%	0.47
MI at 30 days	1.9%	1.7%	0.65
Stroke at 30 days	0.4%	0.6%	0.30
PCI success	95.2%	95.4%	0.83
Access site crossover	2.0%	7.6%	<0.0001
Major vascular complications	3.7%	1.4%	<0.0001
Access site major bleeding	0.3%	0.2%	Not provided
Symptomatic radial occlusion	NA	0.2%	NA
Procedure time (min)	35	34	0.62
Fluoroscopy time (min)	8.0	9.3	<0.0001
Contrast volume (mL)	180	181	0.87
Patient prefers radial access for next procedure	50.7%	90.2%	<0.0001

Modified from Jolly SS, Yusuf S, Cairns J, et al: Radial versus femoral access for coronary angiography and intervention in patients with acute coronary syndromes (RIVAL): A randomised, parallel group, multicentre trial. *Lancet* 377:1409, 2011.

provides the only circulation to the forearm and hand (i.e., it is a functional end-artery), any compromise of the brachial artery can lead to severe ischemic complications in the hand.

The radial artery approach (see Chapters 19 and 20) has gained in popularity as an alternative to femoral access in patients with significant peripheral vascular disease, particularly in obese patients, in whom direct compression of the radial artery reduces bleeding complications.^{44,45} The radial approach provides direct access to the ascending aorta and has the unique advantage of allowing immediate mobilization following PCI. An Allen test is useful to assess flow to the hand before radial artery cannulation. Tortuosity of the brachiocephalic trunk may limit use of the approach in 2% to 3% of patients. The small size of the radial artery limits the size of guiding catheters that can be used during PCI (typically 5F or 6F for women and 7F for men). Transradial access is associated with a generally lower rate (2%) of vascular complications.⁴⁶ A meta-analysis suggested that radial access reduced major bleeding in comparison to femoral access.⁴⁷ The RIVAL (Radial vs Femoral Access for Coronary Intervention) trial randomly assigned patients to either femoral or radial access; no significant difference was found in the primary endpoint of major ischemic events or bleeding⁴⁸ (Table 55-1), but the rate of vascular complications was significantly reduced with the radial approach.

Vascular Access Complications

Vascular access site complications occur after 3% to 7% of femoral PCIs and lead to significantly increased length of hospital stay, total cost, and morbidity and mortality. Complications range from relatively minor access site hematomas, to life-threatening retroperitoneal bleeding requiring emergency blood transfusion, to damage to the vasculature necessitating prompt surgical intervention. Factors predisposing patients to increased risk for serious vascular

complications following PCI include older age, female sex, larger vascular sheath size, low body mass index, renal insufficiency, and degree of anticoagulation during the procedure. The location of the entry point for transfemoral access predicts the risk and type of vascular complication (see Chapter 19). If the access site is above the level of the inguinal ligament, the risk for retroperitoneal hemorrhage increases substantially. If the access site is distal to the femoral bifurcation, pseudoaneurysms (0.4%) and arteriovenous fistulas (0.2%) may occur. Major vascular complications of the femoral approach include limb-threatening ischemia (0.1%) and retroperitoneal hemorrhage (0.4%), which are associated with a 2- to 10-fold increased risk for death in the first 30 days following the PCI procedure.

Vascular Closure Devices

Vascular access closure devices were introduced in the mid-1990s as a new way of managing access sites following femoral access procedures. Vascular closure devices reduce the time to ambulation, increase patient comfort following PCI, and facilitate efficient case flow in the catheterization laboratory.⁴⁹

Currently approved vascular closure devices fall into three categories: (1) sealant devices include collagen-based and thrombin-based systems that leave no mechanical anchor inside or outside the vessel; (2) mechanical closure devices include suture-mediated and nitinol clip-based systems and provide immediate secure closure to the vessel; and (3) hybrid closure devices, such as the dissolvable Angio-Seal device (St. Jude Medical, Minneapolis), use a combination of collagen sealant and internal mechanical closure to induce rapid hemostasis.⁵⁰ Although each device has proved to be relatively safe and effective, a lack of comparative data prohibits evaluation of the relative risks and benefits associated with each device. Meta-analyses have concluded that vascular closure devices do not lower the risk for vascular complications when compared with manual hemostasis, but infections may occur more often with suture-based closure devices, and occlusions are found more often with hybrid devices. Registry analyses have suggested that closure devices reduce bleeding complications in selected patients,⁵¹ but randomized clinical trials are necessary to validate this finding.

CORONARY DEVICES

Over the past three decades, steady improvements in the equipment used for coronary revascularization (e.g., reductions in device profile and improvements in catheter flexibility) have been supplemented by the introduction of periodic “transformational technology,” such as coronary stents and, more recently, DESs, which have extended the scope and breadth of clinical practice. The type of lesions amenable to PCI has become progressively more complex over this period, and the outcomes associated with the use of these devices have progressively improved. A brief overview of currently available coronary devices follows.

Balloon Angioplasty

Balloon angioplasty expands the coronary lumen by stretching and tearing the atherosclerotic plaque and vessel wall and, to a lesser extent, by redistributing atherosclerotic plaque along its longitudinal axis. Elastic recoil of the stretched vessel wall generally leaves a 30% to 35% residual diameter stenosis, and the vessel expansion can result in propagation of coronary dissections and lead to abrupt vessel closure in 5% to 8% of patients. Although stand-alone balloon angioplasty is rarely used other than for very small (<2.25 mm) vessels, balloon angioplasty remains integral to PCI for predilating lesions before stent placement, deploying coronary stents, and further expanding stents after deployment.

Most enhancements in balloon technology are related to the development of low-profile (deflated diameter = 0.7 mm) balloons that can be tracked more readily through tortuous anatomy and noncompliant balloons that can be inflated to pressures in excess of 20 atm without

overexpansion or rupture. A modification of balloon angioplasty includes a focused-force dilation in which a scoring blade or guide-wire external to the balloon concentrates the dilating force and resists balloon slippage during inflation. The Cutting Balloon (Boston Scientific Corp., Natick, Mass) and the AngioScore catheter (AngioScore, Inc., Fremont, Calif) are focused-force balloon angioplasty systems that are currently used in a small minority (<5%) of PCIs. They are sometimes useful in restenotic stent lesions to prevent slippage of the balloon during inflation.

Coronary Atherectomy

Atherectomy refers to removal (rather than simple displacement) of the obstructing atherosclerotic plaque. By removing plaque or improving lesion wall compliance in calcified or fibrotic lesions, atherectomy can provide a larger final minimal lumen diameter than can be achieved by balloon angioplasty alone. Atherectomy was performed in 30% of interventional procedures between 1992 and 1994, but its use fell dramatically with the availability of coronary stents. Fewer than 5% of current procedures involve the use of atherectomy, most often rotational atherectomy in combination with coronary stents.

The Rotablator Rotational Atherectomy System (Boston Scientific) is the most commonly used atherectomy device and removes atheromatous plaque by abrasion of the inelastic calcified plaque with microscopic (20 to 50 μ m) diamond chips embedded on the surface of a rapidly rotating (160,000 rpm) olive-shaped atherectomy burr. Such abrasion generates 2- to 5- μ m microparticles that pass through the coronary microcirculation for removal by the reticuloendothelial system. The burrs travel over a specialized 0.009-inch guidewire and are available in diameters ranging from 1.25 to 2.50 mm. In the setting of severe calcification, smaller (1.25 mm) burrs can be used initially, followed by larger burrs in 0.25- to 0.50-mm increments up to 70% of the reference vessel diameter. Aggressive rotational atherectomy techniques do not provide a restenosis advantage over more conservative methods and tend to increase acute procedural complications such as distal embolization or coronary perforation. Rotational atherectomy does not appear to reduce restenosis in noncalcified vessels any more than balloon angioplasty does. Rotational atherectomy is currently reserved for ostial and heavily calcified lesions that cannot be dilated with balloon angioplasty or those that prevent the delivery of coronary stents. Rotational atherectomy is generally limited to abrasion of superficial calcification with a single 1.5- or 1.75-mm burr to improve lesion compliance (plaque modification) before the lesion is treated definitively by balloon dilation and stent placement. Rotational atherectomy is presently used in fewer than 5% of PCI procedures (Fig. 55-6).

Thrombectomy and Aspiration Devices

The AngioJet rheolytic thrombectomy catheter (Possis Medical, Inc., Minneapolis, Minn) was introduced as a dedicated device for thrombus removal through dissolution and aspiration of the thrombus. High-speed saline jets within the tip of the catheter create intense local suction via the Venturi effect; surrounding blood, thrombus, and saline are pulled into the lumen of the catheter opening and the debris is propelled proximally through the catheter lumen. Rheolytic thrombectomy was superior to a prolonged intraluminal urokinase infusion in patients with a large thrombus, but its routine use in patients with STEMI was not associated with improvement in infarct size on single photon emission computed tomography (SPECT) imaging and may have caused more complications. Rheolytic thrombectomy may still be useful in clinical practice when a large angiographic thrombus is located in a native vessel or SVG.

Newer, lower-profile aspiration catheters that use 6F guiding catheters have been developed as alternatives to rheolytic thrombectomy in patients with thrombus-containing lesions. Although simpler to use, these techniques may be slightly less effective (particularly with partially organized thrombus) than rheolytic thrombectomy, but the risk for distal particulate embolization and device-related trauma in

FIGURE 55-6 Rotational atherectomy of an undilatable left anterior descending artery. **A**, A heavily calcified diffuse lesion in the left anterior descending artery is generally considered undilatable with conventional balloon techniques. **B**, A 1.5-mm rotational atherectomy burr revolving at 160,000 rpm is advanced to ablate the calcified lesion. **C**, A 3-mm × 28-mm stent can then be advanced across the blockage and inflated to 16 atm. Full stent expansion is unlikely to occur without pretreatment with rotational atherectomy. **D**, The final angiographic result shows no residual stenosis and normal flow into the distal vessel.

smaller vessels may be lower with these aspiration catheters. In a multicenter study of 1071 patients with STEMI who were randomly assigned to a thrombus aspiration group or a conventional PCI group, a myocardial blush grade of 0 or 1 occurred in 17.1% of the patients in the thrombus aspiration group and in 26.3% of those in the conventional PCI group ($P < 0.001$).⁵² At 30 days the rate of death in patients with a myocardial blush grade of 0 or 1, 2, and 3 was 5.2%, 2.9%, and 1.0%, respectively ($P = 0.003$), and the rate of adverse events was 14.1%, 8.8%, and 4.2%, respectively ($P < 0.001$).⁵³ Meta-analysis of the data suggests that simple manual thrombus aspiration before PCI reduces mortality in patients undergoing primary PCI (Fig. 55-7).⁵³

Embolic Protection Devices

The advent of embolic protection systems has reduced the risk for postprocedural adverse events following SVG PCI. Although embolization of atherosclerotic debris was not considered a major complication during the early years of native coronary balloon angioplasty, it is now recognized as a potential cause of distal myocardial necrosis after PCI, particularly in friable SVG lesions. Distal embolization causes postprocedural elevation of cardiac enzymes in almost 20% of cases after SVG PCI, and this enzyme elevation is associated with substantial morbidity and mortality. Numerous additional occlusive and filter-based distal protection systems, as well as proximal occlusion devices, have undergone evaluation for use in

SVG interventions,^{23,54} but currently the filter devices are most commonly available. Despite their potential benefit in preventing thromboembolization in patients with STEMI, none of the embolic protection devices have reduced MI size with primary intervention, for which thrombus aspiration remains the mainstay of therapy.

Distal Embolic Filters

Distal filters are advanced across the target lesion in their smaller collapsed state, and withdrawal of the retaining sheath allows the filters to open and expand against the vessel wall. The filters then remain in place to catch any liberated embolic material larger than the pore size (usually 120 to 150 μm) of the filter during intervention. At the end of the intervention the filters are collapsed by using a sheath, and the captured embolic material is removed from the body. This type of device has the advantage of maintaining antegrade flow during the procedure and allowing intermittent injection of contrast material to visualize the underlying anatomy, but it has the potential disadvantage of allowing debris with a diameter smaller than the pore size of the filter to pass (Fig. 55-8).

Coronary Stents

Coronary stents have emerged as the predominant form of PCI and are currently used in more than 90% of PCI procedures worldwide. Coronary stents act as scaffolds for arterial dissection flaps, thereby lowering the incidence of vessel closure and need for emergency CABG; they also

lessen the frequency of restenosis because of their effect in preventing arterial recoil, which is the primary mechanism of restenosis with balloon angioplasty. Despite the late clinical improvement in comparison to balloon angioplasty, restenosis after coronary stent placement occurs in some patients as a result of excessive intimal hyperplasia within the stent. A number of second-generation balloon-expandable stents were introduced between 1997 and 2003; they vary in metallic composition (i.e., cobalt chromium or layered metals versus solid 316 L stainless steel), strut design, stent length, delivery and deployment system, and arterial surface coverage, among other factors. These modifications enhanced flexibility and ease of delivery of the stent while also improving vessel scaffolding and side branch access.

The early use of coronary stents was limited by high (3% to 5%) subacute thrombosis rates despite aggressive antithrombotic therapy with aspirin, dipyridamole, periprocedural low-molecular-weight dextran, and an uninterrupted transition from intravenous heparin to oral warfarin. Subacute thrombosis produced profound clinical consequences that resulted in an untoward outcome (e.g., death, MI, or emergency revascularization) in virtually every such patient. Lower frequencies of subacute stent thrombosis (roughly 0.5% to 1.0%) have resulted from the use of high-pressure stent deployment and with a drug regimen that includes aspirin and an ADP receptor antagonist (clopidogrel, prasugrel, or ticagrelor) (see Chapter 82) started just before or after stent placement.

FIGURE 55-7 In this meta-analysis of patients with STEMI undergoing primary PCI, simple manual thrombus aspiration was associated with lower mortality than were mechanical aspiration and embolic protection devices. (From Bavry AA, Kumbhani DJ, Bhatt DL: Role of adjunctive thrombectomy and embolic protection devices in acute myocardial infarction: A comprehensive meta-analysis of randomized trials. *Eur Heart J* 29:2989, 2008.)

Even though coronary BMSs reduce the incidence of angiographic and clinical restenosis when compared with balloon angioplasty, angiographic restenosis (follow-up diameter stenosis >50%) still occurs in 20% to 30% of patients, and clinical restenosis (recurrent angina caused by restenosis in the treated segment) develops in 10% to 15% of patients in the first year after treatment. Restenosis with BMSs occurs more often in patients with small vessels, long lesions, and diabetes mellitus, among other factors. Adjunctive pharmacologic therapy has not prevented restenosis after stent placement.

Several mechanical treatments of in-stent restenosis have been attempted, including balloon redilation, removal of in-stent hyperplasia by means of atherectomy, and repeated BMS placement. Brachytherapy using beta or gamma sources modestly improved this outcome for in-stent restenosis, but brachytherapy has several limitations, including the requirement for a radiation therapist, a tendency for late “catch-up” restenosis, and inhibition of endothelialization, which markedly increases the risk for thrombosis if another stent is implanted in the same vessel segment. Brachytherapy was found to be inferior to DES placement for treating restenosis in two randomized studies.^{55,56}

BMSs are currently used in 10% to 30% of patients undergoing PCI, most often because of an inability to take long-term dual antiplatelet therapy; in larger (>4.0 mm) vessels, in which the risk for restenosis is lower; and in acute MI, for which the issues related to patient compliance are more difficult to ascertain.

Drug-Eluting Stents

DESs were developed in the early 2000s to provide sustained local delivery of an antiproliferative agent at the site of vessel wall injury. The three components of current DESs are a balloon-expandable stent, a durable or resorbable polymer coating that provides sustained drug delivery, and the pharmacologic agent used to limit intimal hyperplasia.

DESs have proven efficacy in patients with focal, de novo, and “workhorse” lesions that include reference vessel diameters between 2.5 and 3.5 mm and lesion lengths between 15 and 30 mm. Additional randomized trials and registries have also demonstrated the benefit of DESs in patients with long (>30 mm in length) and small (<2.5 mm) vessels, chronic total occlusions, SVG and internal mammary artery disease, in-stent restenosis, and STEMI.⁵⁷ With the expanded follow-up of patients receiving DESs, it appears that DES placement may require extended (up to 1 year) therapy with a combination of aspirin and clopidogrel to prevent stent thrombosis.⁵⁸ Moreover, even after 1 year

there is a low (0.2% to 0.6%) annual rate of very late stent thrombosis, which warrants a careful discussion of the risks, benefits, and alternative therapies in candidates for PCI. Ongoing trials will determine whether longer (or shorter) durations of therapy are sufficient.⁵⁹⁻⁶¹ The risk for late and very late stent thrombosis appears to be related to endothelial dysfunction and an abnormal healing response to the vessel wall attributable to the durable stent polymer.⁶² Although some trials⁶³ and meta-analyses⁶⁴ of more recently approved DESs with new polymers show a reduction in stent thrombosis when compared with earlier DESs, other large randomized trials have not.⁶⁵

Sirolimus-Eluting Stents

The CYPHER stent (Cordis, Warren, NJ) contains sirolimus, a naturally occurring immunosuppressive agent that causes cytostatic inhibition of cell proliferation. Sirolimus is released from a biostable polymer over a 30-day period. The pivotal SIRIUS (Sirolimus-Eluting Stent in De-Novo Native Coronary Lesions) trial included 1058 patients with workhorse lesions who were randomly assigned to treatment with a sirolimus-eluting stent or a BMS. The primary clinical endpoint of 8-month target vessel failure, which included target vessel revascularization, death, or MI, was reduced from 21% in patients treated with BMSs to 8.6% in patients treated with sirolimus-eluting stents ($P < 0.001$). The rate of target vessel revascularization was reduced from 16.6% in BMSs to 4.1% in sirolimus-eluting stents at 1 year ($P < 0.001$) and was sustained at 5 years.^{66,67} The cumulative incidence of MI or revascularization attributed to remote segments of the target vessel did not differ between the two groups. Even though manufacture of the CYPHER stent ceased in 2011, other sirolimus-eluting stents continue to be manufactured and sold outside the United States.

Paclitaxel-Eluting Stents

The TAXUS stent (Boston Scientific) is composed of a stainless steel stent platform, a polyolefin polymer derivative, and the microtubular stabilizing agent paclitaxel, which has anti-inflammatory effects while also inhibiting both cell migration and division. Release of paclitaxel is completed within 30 days of implantation, although a substantial portion (>90%) of the paclitaxel remains within the polymer indefinitely. The pivotal TAXUS-IV trial randomly assigned 1314 patients with single de novo coronary lesions to either a TAXUS stent or an identical-appearing BMS. The rate of ischemia-driven target vessel revascularization at 9 months was reduced from 11.3% to 3% and remained significantly reduced at 12 months (from 17.1% to 7.1%) in patients with paclitaxel-eluting stents ($P < 0.001$).

Zotarolimus-Eluting Stents

Zotarolimus (also known as ABT-578) is another rapamycin analogue released from a phosphorylcholine (PC)-coated stent that has been evaluated in the Endeavor stent (Medtronic Vascular, Santa Rosa, Calif). In the ENDEAVOR-II trial, 1197 patients were assigned to treatment with the Endeavor zotarolimus-eluting PC polymer-coated stent or with the same BMS without the drug or the polymer coating.⁶⁸ The 9-month primary endpoint of target vessel failure was reduced from 15.1% with the BMS to 7.9% with the Endeavor stent ($P < 0.0001$). In-stent late loss was reduced from 1.03 to 0.61 mm in patients treated with the Endeavor stent ($P < 0.001$), and the rate of in-segment restenosis was reduced from 35% to 13.2% with the Endeavor stent ($P < 0.0001$). A significant reduction in target vessel revascularization was associated with use of the Endeavor stent, and it persisted to 4 years.⁶⁸ The ENDEAVOR-III trial compared the Endeavor stent with the CYPHER in a 436-patient study (3:1 randomization) but failed to meet the primary endpoint of noninferior in-segment late loss at 8 months (0.34 mm with zotarolimus-eluting stents versus 0.13 mm with sirolimus-eluting stents), with higher in stent late loss (0.60 mm and 0.15 mm, respectively, $P < 0.001$). Target lesion revascularization was not significantly different between the two groups (6.3% and 3.5%, respectively, $P = 0.34$). At the 3-year follow-up the occurrence of death and MI was reduced in patients treated with the Endeavor stent, but that of target vessel revascularization was no different.⁶⁹ The ENDEAVOR-IV trial was a prospective, randomized, single-blind, controlled trial in which the safety and efficacy of the zotarolimus-eluting

FIGURE 55-8 Filters for distal protection. **A**, The Spider Filter (ev3, Minneapolis); **B**, Angioguard Device (Cordis, Warren, NJ); **C**, EPI Filterwire (Boston Scientific, Natick, Mass); **D**, AccUNET device (Guidant, Santa Clara, Calif); **E**, MedNova (Abbott, Chicago); **F**, Rubicon Filter (Boston Scientific); **G** and **H**, The Interceptor Filter (Medtronic Vascular, Santa Rosa, Calif) in longitudinal view (**G**) and axial view (**H**).

stent was compared with that of the paclitaxel-eluting stent in 1548 patients with single de novo coronary lesions. The primary endpoint was a composite of cardiac death, MI, or target vessel revascularization, and the Endeavor stent was noninferior to the TAXUS stent. In addition, fewer periprocedural MIs occurred with zotarolimus-eluting stents (0.5% versus 2.2%; $P = 0.007$) because of less side branch occlusion in patients with these stents.⁷⁰ Although 8-month angiographic restenosis was improved after paclitaxel-eluting stent therapy, at 12 months the frequency of target lesion revascularization was similar between zotarolimus-eluting stents and paclitaxel-eluting stents (4.5% versus 3.8%; $P = 0.228$), especially in those without planned angiographic follow-up (3.6% versus 3.2%; $P = 0.756$), and these results persisted for 2 years.⁷¹ More recently, a large randomized trial powered to compare stent thrombosis at 3 years between the Endeavor stent and the CYPHER stent showed no difference in the primary endpoint of definite or probable stent thrombosis.⁶⁵

Everolimus-Eluting Stent

The Xience stent (Abbott Vascular, Santa Rosa, Calif) uses the cobalt chromium Vision stent, a durable fluoropolymer, and everolimus, a rapamycin analogue that has both immunosuppressive and antiproliferative effects. Based on initial studies in which the use of an absorbable poly-L-lactic acid (PLA) polymer was evaluated, the SPIRIT program has shown a reduction in late lumen loss comparable to that achieved with the CYPHER stent. SPIRIT III was a prospective, randomized, single-blind, controlled trial that enrolled 1002 patients undergoing PCI for lesions 28 mm or less in length and with a reference vessel diameter of between 2.5 and 3.75 mm.⁷² Angiographic in-segment late loss was significantly less in the everolimus-eluting stent group than in the paclitaxel group (0.14 versus 0.28 mm; $P \leq 0.004$).⁷² The everolimus stent was noninferior to the paclitaxel stent in terms of the rate of target vessel failure at 9 months (7.2% versus 9.0%, respectively; $P < 0.001$ for noninferiority). The everolimus stent

was associated with significant reductions in composite major adverse cardiac events at 9 months when compared with the paclitaxel stent (4.6% versus 8.1%; $P = 0.03$) and at 1 year (6.0% versus 10.3%; $P = 0.02$) because of fewer MIs and target lesion revascularization procedures.⁷² SPIRIT IV, a larger randomized comparison of the everolimus and paclitaxel stents in 3687 patients, found similar benefits of the everolimus stent, with significantly lower rates of target lesion failure, MI, stent thrombosis, and ischemia-driven target lesion revascularization.⁷³

Bioabsorbable Polymers and Drug-Eluting Stents

Bioabsorbable polymers have the potential benefit of no polymer remaining after the period required for reduction of neointimal hyperplasia, therefore limiting vascular reaction and toxicity. These polymers have been used on conventional metal stents to elute drug^{74,75} but can also stand alone as fully biodegradable stents.^{76,77} Early randomized trials of both these approaches have shown that these new stents may hold significant promise.

ANTIPLATELET AGENTS (See Chapter 82)

Aspirin

Aspirin irreversibly inhibits cyclooxygenase and thus blocks the synthesis of thromboxane A_2 , a vasoconstriction agent that promotes platelet aggregation.⁷⁸ Aspirin substantially reduces periprocedural MI caused by thrombotic occlusions when compared with placebo and is standard for all patients undergoing PCI. The inhibitory effect of aspirin occurs within 60 minutes, and its effect on platelets lasts for up to 7 days after discontinuation. Although the minimum effective aspirin dosage in the setting of PCI remains uncertain, patients maintained on a regimen of daily chronic aspirin therapy should receive 81 to 325 mg aspirin before PCI (see [PCI Guidelines](#) at the end of this chapter). Patients not already taking daily long-term aspirin therapy should be given 325 mg of aspirin at least 2 hours and preferably 24 hours before PCI is performed. After PCI, aspirin should be continued indefinitely in patients without allergy, and a lower dose (e.g., 81 mg) may be preferable to decrease the risk for gastrointestinal bleeding risk (see [PCI Guidelines](#)).

Adenosine Diphosphate Receptor Antagonists

Thienopyridine derivatives cause irreversible platelet inhibition through their effects on the $P2Y_{12}$ ADP receptor, which can activate the glycoprotein (GP) IIb/IIIa complex. Because aspirin and the thienopyridines have distinct mechanisms of action, their combination inhibits platelet aggregation to a greater extent than either agent does alone. Use of the combination of aspirin and clopidogrel (or previously, ticlopidine) for 14 to 28 days was essential to prevent stent thrombosis after BMS placement. The combination of aspirin and clopidogrel was also found to reduce death, MI, and urgent revascularization within 12 months in patients undergoing PCI in the setting of NSTEMI and unstable angina and in those undergoing elective PCI. Recent studies have suggested that a loading dose of 600 mg of clopidogrel rather than 300 mg results in more rapid (<2 hours) platelet inhibition and improved clinical outcomes, including lower rates of stent thrombosis. Additional clopidogrel loading with 300 or 600 mg may also be used in patients being treated with chronic maintenance clopidogrel therapy, although whether this actually improves clinical outcomes is unclear.⁷⁹ The need for pretreatment with clopidogrel is more controversial inasmuch as the improved clinical outcomes need to be balanced against the potential risk for bleeding should CABG be necessary. Current guidelines recommend that a 600-mg loading dose of clopidogrel be administered before or during PCI (see [PCI Guidelines](#)). All post-PCI patients treated with a DES should receive clopidogrel (75 mg daily) for at least 12 months if they do not have a high risk for bleeding. For post-PCI patients receiving a BMS, clopidogrel should be given for a minimum of 1 month and ideally up to 12 months (unless the patient has an increased risk for bleeding,

in which case it should be given for a minimum of 2 weeks) (see [PCI Guidelines](#)).

Prasugrel, a thienopyridine, is a more potent $P2Y_{12}$ ADP receptor inhibitor with a more rapid onset of action and higher levels of platelet inhibition than higher-dose clopidogrel.⁸⁰ In a study of 13,608 patients with moderate- to high-risk acute coronary syndromes undergoing scheduled PCI and randomly assigned to receive prasugrel (60-mg loading dose and 10-mg daily maintenance dose) or clopidogrel (300-mg loading dose and 75-mg daily maintenance dose) for 6 to 15 months, the primary efficacy endpoint—a composite of death from cardiovascular causes, nonfatal MI, or nonfatal stroke—occurred in 12.1% of patients receiving clopidogrel and in 9.9% of those receiving prasugrel ($P < 0.001$).⁸¹ Prasugrel was also associated with significant reductions in rates of MI (9.7% for clopidogrel versus 7.4% for prasugrel, $P < 0.001$), urgent target vessel revascularization (3.7% versus 2.5%, $P < 0.001$), and stent thrombosis (2.4% versus 1.1%, $P < 0.001$).⁸¹ On the other hand, major bleeding was observed in 2.4% of patients receiving prasugrel and in 1.8% of patients receiving clopidogrel ($P = 0.03$), with more frequent rates of life-threatening bleeding occurring in the prasugrel group (1.4% versus 0.9% with clopidogrel, $P = 0.01$), including fatal bleeding (0.4% versus 0.1%, respectively, $P = 0.002$).^{81,82} Among patients treated with clopidogrel, carriers of reduced-function *CYP2C19* alleles had significantly lower levels of active metabolite, diminished platelet inhibition, and higher rates of adverse cardiovascular events.⁸³ Such a relationship was not found in patients treated with prasugrel. Further research will be necessary to determine whether point-of-care platelet assays or determination of genetic polymorphisms can help in allocating therapy, although to date this type of testing does not appear to be clinically useful.⁸⁴ In patients with an acute coronary syndrome undergoing PCI who are at low bleeding risk, prasugrel may be given in a 60-mg loading dose as soon as possible after definition of the coronary anatomy and 10 mg daily continued for 12 months after stent placement (see [PCI Guidelines](#)).

Ticagrelor, a reversible oral $P2Y_{12}$ receptor antagonist, provides faster, greater, and more consistent ADP receptor inhibition than does clopidogrel.⁸⁵ A multicenter, double-blind trial of 18,624 patients with an acute coronary syndrome, with or without ST-segment elevation, assigned patients randomly to treatment with ticagrelor (180-mg loading dose, 90 mg twice daily thereafter) or clopidogrel (300- to 600-mg loading dose, 75 mg daily thereafter) for 12 months. The primary endpoint—a composite of death from vascular causes, MI, or stroke at 12 months—occurred in 9.8% of patients receiving ticagrelor and in 11.7% of those receiving clopidogrel (hazard ratio, 0.84; $P < 0.001$).⁸⁶ Ticagrelor was also associated with significant reductions in MI alone (5.8% versus 6.9% in the clopidogrel group, $P = 0.005$) and in death from vascular causes (4.0% versus 5.1%, respectively, $P = 0.001$).⁸⁶ No significant difference in overall rates of major bleeding was observed between the ticagrelor and clopidogrel groups (11.6% and 11.2%, respectively; $P = 0.43$), but ticagrelor was associated with a higher rate of major bleeding not related to CABG (4.5% versus 3.8%, $P = 0.03$).⁸⁶

Current evidence suggests that in the absence of risk factors for bleeding, dual antiplatelet therapy should continue for at least 12 months after BMS and DES placement. Prolonged thienopyridine therapy not only reduces late stent thrombosis but also prevents MI by thrombi that complicate plaque remote from the initial intervention. Indefinite aspirin and clopidogrel therapy is recommended in patients undergoing brachytherapy, and long-term higher doses (150 mg daily) of clopidogrel may be considered in patients in whom stent thrombosis may be catastrophic, such as those with unprotected left main artery stenting or with stenting of the last remaining vessel.¹²

Glycoprotein IIb/IIIa Inhibitors

Thrombin and collagen are potent platelet agonists that can cause release of ADP and serotonin and activate GP IIb/IIIa receptors on the platelet surface (see [Chapter 82](#)). Functionally active GP IIb/IIIa has a role in the “final common pathway” of platelet aggregation by binding fibrinogen and other adhesive proteins that bridge adjacent platelets. Three intravenous GP IIb/IIIa inhibitors are approved for

clinical use. Studies supporting the use of these agents during PCI were performed before the widespread use of dual antiplatelet therapy, however, and use of these agents has been reevaluated in this context.

Abciximab is a chimeric human-murine monoclonal antibody that irreversibly binds to the platelet GP IIb/IIIa receptor on human platelets. It also binds to the vitronectin ($\alpha_v\beta_3$) receptor found on platelets and to vessel wall endothelial and smooth muscle cells. The recommended dosage of abciximab is a 0.25 mg/kg by intravenous bolus, followed by a continuous intravenous infusion of 0.125 $\mu\text{g/kg/min}$ (to a maximum of 10 $\mu\text{g/min}$) for 12 hours. Abciximab can be administered safely in patients with renal insufficiency, and platelet infusions can reverse the effect of this agent (although repeated transfusions may be necessary).

Eptifibatide is a cyclic peptide derivative that reversibly binds GP IIb/IIIa. The double eptifibatide bolus (180- $\mu\text{g/kg}$ boluses 10 minutes apart) and infusion dose (2.0 $\mu\text{g/kg/min}$ for 18 to 24 hours) result in sufficient platelet inhibition to prevent ischemic events in patients undergoing PCI. Addition of eptifibatide to a 600-mg loading dose of clopidogrel also causes incremental platelet inhibition. The eptifibatide infusion must be reduced to 1 $\mu\text{g/kg/min}$ in patients with a creatinine clearance lower than 50 mL/min. Platelet transfusions do not reverse the platelet inhibition with eptifibatide, although by 4 hours after cessation of the infusion, patients have safely undergone CABG.

Tirofiban, a peptidomimetic small molecule, has also undergone evaluation for its adjunctive benefit during urgent PCI but was found to be inferior to abciximab for prevention of ischemic events during PCI. The recommended dosage is an initial rate of 0.4 $\mu\text{g/kg/min}$ for 30 minutes and then continued at 0.1 $\mu\text{g/kg/min}$. Patients with severe renal insufficiency (creatinine clearance <30 mL/min) should receive half the usual rate of infusion. Subsequent studies have suggested that the tirofiban bolus dose given in the initial PCI studies may not have produced an optimal antiplatelet effect during PCI and that larger bolus doses can improve the inhibition of platelet aggregation.⁸⁷

The GP IIb/IIIa inhibitors have demonstrated improvement in clinical outcomes within the first 30 days after PCI, primarily by reducing ischemic complications, including periprocedural MI and recurrent ischemia. They are particularly useful in patients with troponin-positive acute coronary syndromes but have no consistent effect in reducing late restenosis. Although GP IIb/IIIa inhibitors differ in their structure, reversibility, and duration, two meta-analyses found no difference between their clinical effects in patients undergoing primary PCI.^{88,89} Bleeding is the major risk associated with GP IIb/IIIa inhibitors, and therefore downward adjustment of the unfractionated heparin dose has been recommended. GP IIb/IIIa inhibitors are recommended in patients with NSTEMI and unstable angina who are not pretreated with clopidogrel, and it is reasonable to administer them to patients with troponin-positive acute coronary syndromes who have also been pretreated with clopidogrel.^{90,91}

ANTITHROMBIN AGENTS

Unfractionated heparin (see Chapter 82) is the most commonly used thrombin inhibitor during PCI. Point-of-care activated clotting time (ACT) monitoring has facilitated heparin dose titration during PCI, and retrospective studies on balloon angioplasty have related the ACT value to clinical outcome after PCI. An ACT in the range of 350 to 375 seconds provided the lowest composite ischemic event rate, although any level of ACT longer than 250 seconds was not associated with any further reductions in ischemic complications with the concomitant use of GP IIb/IIIa inhibitors. More recent studies in the thienopyridine era have failed to correlate ischemic outcomes with the level of anticoagulation achieved with unfractionated heparin during coronary stent placement. Weight-adjusted heparin dosing regimens of 50 to 70 IU/kg help avoid “overshooting” the ACT. Sufficient unfractionated heparin should be administered during PCI to achieve an ACT longer than 250 to 300 seconds if no GP IIb/IIIa inhibitor is given and longer than 200 to 250 seconds if a GP IIb/IIIa inhibitor is given. Routine

use of intravenous heparin after PCI is no longer indicated. If no closure device has been used, early sheath removal is encouraged when the ACT falls to less than 150 to 180 seconds.

Low-Molecular-Weight Heparin (See Chapter 82)

Enoxaparin is considered a reasonable alternative to unfractionated heparin in patients with non-ST-segment elevation acute coronary syndromes undergoing PCI (see Chapter 53), but difficulty monitoring the levels of anticoagulation in the event that PCI is performed has limited its clinical use at many centers.⁹² The SYNERGY (Superior Yield of the New Strategy of Enoxaparin, Revascularization and Glycoprotein IIb/IIIa Inhibitors) trial prospectively randomly assigned 10,027 high-risk patients with non-ST-segment elevation acute coronary syndrome with an intended early invasive strategy to treatment with subcutaneous enoxaparin or to intravenous unfractionated heparin. The 30-day primary efficacy outcome, a composite clinical endpoint of all-cause death or nonfatal MI, occurred in 14% of the patients assigned to enoxaparin and in 14.5% of the patients assigned to unfractionated heparin. More TIMI (Thrombolysis in Myocardial Infarction) major bleeding was observed in patients treated with enoxaparin (9.1% versus 7.6%, $P = 0.008$). Risk for bleeding was highest in patients who received “crossover” therapy with unfractionated heparin and enoxaparin. When enoxaparin is given before PCI, empiric dose algorithms have been designed to guide additional anticoagulation therapy during PCI. If the last dose of enoxaparin was administered less than 8 hours before PCI, no additional antithrombin is needed. If the last dose of enoxaparin was given between 8 and 12 hours, a 0.3-mg/kg bolus of intravenous enoxaparin should be administered. If the dose was administered more than 12 hours before PCI, conventional anticoagulation therapy is indicated.

Bivalirudin

Bivalirudin is a direct thrombin inhibitor that has been used as an alternative to unfractionated heparin in patients undergoing PCI. Bivalirudin generally causes fewer bleeding complications than unfractionated heparin does because of its shorter half-life (25 minutes) and more predictable bioavailability.⁹³ Bivalirudin is also accessible to clot-bound thrombin because its anticoagulant effect does not depend on binding with antithrombin. Bivalirudin was not inferior to the combination of unfractionated heparin and a GP IIb/IIIa inhibitor in 6010 “low-risk” patients in the REPLACE-2 (Second Randomized Evaluation in PCI Linking Angiomax to Reduced Clinical Events) trial. In a larger study of 13,819 patients with unstable angina and NSTEMI, bivalirudin alone was compared with bivalirudin plus a GP IIb/IIIa inhibitor and with heparin plus a GP IIb/IIIa inhibitor. Using a composite ischemia endpoint of death, MI, or unplanned revascularization for ischemia and major bleeding to determine the net clinical benefit, bivalirudin alone, as opposed to heparin plus a GP IIb/IIIa inhibitor, showed noninferiority in the composite ischemia endpoint (7.8% and 7.3%, respectively) and significantly reduced rates of major bleeding (3.0% versus 5.7%, $P < 0.001$), which resulted in a better net clinical outcome (10.1% versus 11.7%, $P = 0.02$). Bivalirudin is considered a reasonable alternative to unfractionated heparin in low-risk patients undergoing PCI and may reduce bleeding complications in higher-risk patients with unstable angina and NSTEMI. Bivalirudin may be safely substituted for unfractionated heparin in patients with acute coronary syndromes⁹⁴ and is a cost-effective alternative to unfractionated heparin plus a GP IIb/IIIa inhibitor.⁹⁵ In a randomized study of 3602 patients with STEMI undergoing primary PCI (see Chapter 52), anticoagulation with bivalirudin alone, as compared with heparin plus GP IIb/IIIa inhibitors, resulted in significantly reduced 30-day rates of major bleeding and net adverse clinical events, including a lower rate of mortality.⁹¹ Adjunctive oral ADP-blocking agents should be given as soon as possible before PCI in patients with acute coronary syndromes.⁹⁶

Factor Xa Inhibitors

Fondaparinux is a pentasaccharide that has anti-factor Xa activity without effects on factor IIa and may cause less bleeding when used

to treat patients with acute coronary syndromes.⁹⁷ The OASIS-5 (Fifth Organization to Assess Strategies in Acute Ischemic Syndromes) trial randomly assigned 20,078 patients with acute coronary syndromes to receive either fondaparinux (2.5 mg daily) or enoxaparin (1 mg/kg of body weight twice daily) for a mean of 6 days. Occurrence of the 9-day primary study endpoint (death, MI, or refractory ischemia) was similar in the two groups (5.8% with fondaparinux and 5.7% with enoxaparin), although the risk for major bleeding at 9 days was markedly lower with fondaparinux than with enoxaparin (2.2% versus 4.1%, $P < 0.001$). This reduction in bleeding was accompanied by an improvement in late mortality in patients treated with fondaparinux. Potential limitations of this approach are the relatively long half-life of fondaparinux and the need for adjunctive anticoagulation with heparin during PCI to avoid the development of catheter thrombi. Fondaparinux was not effective in reducing ischemic events in patients undergoing primary PCI for STEMI (see [PCI Guidelines](#)).

OUTCOMES FOLLOWING PERCUTANEOUS CORONARY INTERVENTION

Procedural success and complication rates are used to measure outcomes after PCI. Early (<30 day) success (e.g., relief of angina; freedom from death, MI, and urgent revascularization) is generally related to the safety and effectiveness of the initial procedure, whereas late (30 days to 1 year) success (e.g., freedom from recurrence of angina, target vessel revascularization, MI, or death) depends on both clinical restenosis and progressive atherosclerosis at remote sites. Substantial improvements in coronary devices (e.g., DESs), in the adjunctive antithrombotics used during PCI (e.g., ADP antagonists, GP IIb/IIIa inhibitors, direct thrombin inhibitors), and in secondary prevention after PCI (e.g., therapy with lipid-lowering agents, beta-adrenergic blockers, antiplatelet drugs; see [Chapter 42](#)) have markedly improved early and late clinical outcomes following PCI.

Early Clinical Outcomes

Anatomic (or angiographic) success after PCI is defined as attainment of a residual diameter stenosis of less than 50%, which is generally associated with at least a 20% improvement in diameter stenosis and relief of ischemia. With the widespread use of coronary stents, the angiographic criterion for success is 20% stenosis or less when stents are used. Procedural success is defined as angiographic success without the occurrence of major complications (death, MI, or CABG) within 30 days of the procedure. Clinical success is defined as procedural success without the need for urgent repeated PCI or surgical revascularization within the first 30 days of the procedure. Several clinical, angiographic, and technical variables can be used to predict the risk for procedural failure in patients undergoing PCI. Major complications include death, MI, or stroke, and minor complications include transient ischemic attacks, vascular complications, contrast-induced nephropathy, and angiographic complications.

Mortality

Although mortality after PCI is rare (<1%), it is higher in the setting of STEMI, in cardiogenic shock, and in patients with previously poor LV function in whom an occlusion develops. Several risk factors for early mortality after PCI have been identified.⁹⁸⁻¹⁰⁰

Myocardial Infarction

Periprocedural MI is one of the most common complications of PCI.¹⁰¹ Two classification systems were previously used to classify MI after PCI: the World Health Organization classification system, which defines MI as an elevation in total creatine kinase (CK) more than two times normal in association with elevation of the CK-MB isoform, and a second system, more commonly used for evaluation of adjunctive pharmacologic agents by the U.S. Food and Drug Administration, in which MI is defined as an elevation in CK-MB three times normal or higher after the procedure. A consensus definition of

periprocedural MI now uses a troponin level elevated more than five times normal when it occurs in conjunction with clinical evidence of MI with symptoms, changes on the electrocardiogram (ECG), angiographic findings, or a new imaging abnormality.¹⁰² In clinical practice, asymptomatic CK-MB elevations (less than five times the upper limit of normal) occur following 3% to 11% of technically successful PCIs and have little apparent clinical consequence. Larger degrees of myonecrosis (CK-MB five to eight times the upper limit of normal) are associated with higher 1-year mortality rates and should be considered a periprocedural MI. Many of these clinically silent infarcts may reflect a higher atherosclerotic burden in patients who suffer such events and may not be truly causal. Troponin T and I elevations occur more commonly than CK-MB elevations, but their prognostic significance over that of CK-MB elevation is not as well established. Spontaneous MI after PCI has much more prognostic importance than periprocedural enzyme elevation.¹⁰³

Urgent Revascularization

Emergency or urgent CABG following PCI is now uncommon and, in the era of coronary stents, results from catastrophic complications during PCI, such as coronary perforation or severe dissection and abrupt closure. Chest pain after PCI is relatively common, and evaluation requires an immediate 12-lead ECG. Recurrent ischemia following PCI as manifested by chest pain, abnormalities on the ECG, and elevated levels of cardiac biomarkers may occur as a result of acute or subacute stent thrombosis, residual dissections, plaque prolapse, side branch occlusion, or thrombus at the treatment site or may be related to residual disease not treated during the initial procedure. In the presence of suspected recurrent ischemia, coronary arteriography is the most expeditious way to identify the cause of the residual ischemia.

Angiographic Complications

Complications that occur during PCI, depending on their severity and duration, may result in periprocedural MI (Videos 55-1 and 55-2). If coronary dissections that extend deeper into the media or adventitia begin to compromise the true lumen of the vessel, clinical ischemia may develop. Even though most intraprocedural dissections can be treated promptly by stenting, significant residual dissections of the treated artery occur in 1.7% of patients. These residual dissections raise the risk for postprocedural MI, need for emergency CABG, and the incidence of stent thrombosis and increase mortality threefold.¹⁰⁴ In addition to barotrauma-induced dissections, dissections attributable to the guiding catheter represent another mechanism for disrupting the coronary vessel and compromising distal flow.

Coronary perforation develops in 0.2% to 0.5% of patients undergoing PCI and is more common with atheroablative devices and hydrophilic wires than with balloon angioplasty or conventional guidewires. Depending on the rate of flow through the vessel perforation, cardiac tamponade and hemodynamic collapse can occur within minutes, thus requiring immediate recognition and treatment of the perforation. Strategies for controlling coronary perforations include reversal of intraprocedural anticoagulation and prolonged inflation (at least 10 minutes) of an oversized balloon at low pressure at the site of the perforation to encourage sealing of the tear in the vessel. Management strategies for perforations include the use of perfusion balloons, which provide a small amount of distal perfusion, and the use of polytetrafluoroethylene (PTFE)-covered stents, which may control free perforations, in addition to decompression of pericardial pressure with prompt pericardiocentesis. Approximately one third of cases of PCI-associated coronary artery perforation require emergency cardiac surgery.

No-reflow is defined as reduced anterograde perfusion in the absence of a flow-limiting stenosis and occurs in up to 2% to 3% of PCI procedures, typically during interventions on degenerated SVGs, during rotational atherectomy, and during acute MI interventions.¹⁰⁵ No-reflow is probably caused by distal embolization of atheromatous and thrombotic debris dislodged by balloon inflation, atherectomy, or stent implantation. Once it occurs, no-reflow can cause severe short- and long-term consequences, including a fivefold increased

**VIDEO 55-1**

Air injected down the right coronary artery.

VIDEO 55-2

Three coronary arteries off the right coronary cusp.

risk for periprocedural MI and a threefold increased risk for death. Although numerous pharmacologic strategies (such as intracoronary sodium nitroprusside) have been used to treat no-reflow, their efficacy in reducing the frequency of subsequent adverse events is still debated.

Stent Thrombosis

With the routine use of a high-pressure stent after dilation and dual antiplatelet therapy following stent implantation, the rate of stent thrombosis has declined to approximately 1% within the first year after stenting, although it can be higher in patients with STEMI or after complex PCI. Certain clinical, angiographic, and procedural factors predispose to its development. Lesion-specific factors that increase the likelihood of stent thrombosis include a residual dissection at the margin of the stent, impaired flow into or out of the stent, small stent diameter (<3 mm), long stent length, and treatment of acute MI. Patient noncompliance with dual antiplatelet therapy, resistance to the antiplatelet effects of aspirin and clopidogrel, and hypercoagulability may also play important roles in the development of stent thrombosis (Table 55-2).

The timing of stent thrombosis is defined as acute (<24 hours), subacute (24 hours to 30 days), late (30 days to 1 year), and very late (>1 year). Traditional definitions of stent thrombosis have included only episodes associated with an acute coronary syndrome and angiographic or pathologic demonstration of thrombosis within the stent or its margins. The Academic Research Consortium has proposed criteria for documentation of all possible stent thrombosis in clinical studies, including the categories of definite stent thrombosis, probable stent thrombosis, and possible stent thrombosis.¹⁰⁶

Early reports suggested an incremental risk (0.2% to 0.5% per year) for very late stent thrombosis occurring 1 year or longer after DES implantation.¹⁰⁷ Inhibition of endothelialization caused by the potent antiproliferative effect of the drugs delivered by DESs may significantly prolong the period of risk for the development of stent thrombosis. Although concerning, these events have not yet been shown to cause a significant increase in late morbidity or mortality, probably because of the benefits of DESs in reducing the need for repeated revascularization procedures and avoidance of the complications associated with the development of in-stent restenosis.^{1,108-110} Ongoing evaluation of the long-term safety of DESs has engendered intense investigation, with efforts focused on determining whether patient- and lesion-specific risk factors, such as insensitivity to aspirin or clopidogrel, may contribute; whether these risks are device-specific

or drug-specific phenomena; and whether prolonged dual antiplatelet therapy may ameliorate these risks. Preliminary data suggest that second-generation DESs have lower rates of stent thrombosis than do first-generation DESs. Intravenous antiplatelet agents, such as the ADP receptor antagonist cangrelor, have the potential to further reduce the rate of periprocedural stent thrombosis.

The not-infrequent scenario of a patient requiring noncardiac surgery in the weeks following PCI can markedly increase the risk for stent thrombosis. Studies of outcomes in patients undergoing noncardiac surgery soon after BMS PCI have documented stent thrombosis occurring in up to 8% in the first 2 weeks following PCI, with risks declining to baseline rates by 8 weeks. This increased risk probably results from the frequent cessation of ADP receptor antagonist treatment before surgery, as well as the hypercoagulable state in the perioperative period.

Late Clinical Outcomes

Ischemic events within the first year after PCI result from one of three processes. Lumen renarrowing requiring repeated revascularization (i.e., target lesion revascularization) occurs in 20% to 30% of patients undergoing balloon angioplasty because of reparative arterial constriction, also known as “negative remodeling.” Clinical restenosis after stent implantation is less common (10% to 20%) and attributable to intimal hyperplasia within the stent. Clinical recurrence caused by restenosis is least common (3% to 5%) after DES placement because of focal tissue growth within the stent or at its margins. Yet another cause of clinical events after PCI is progression of coronary atherosclerosis at a site remote from that treated earlier by PCI. Death and MI can also result from sudden rupture of a plaque that is remote from the site of the initial intervention.

These processes can be partially distinguished by the timing of their occurrence. Clinical restenosis resulting from lumen renarrowing at the site of PCI generally develops within the first 6 to 9 months after PCI, whereas death and MI because of plaque instability may occur at any point after PCI at a low but constant rate (1% to 2% risk per year). Predictors of higher risk for all-cause late mortality include advanced age, reduced LV function, congestive heart failure, diabetes mellitus, a higher number of diseased vessels, inoperable disease, or severe comorbid conditions. A 95% 10-year survival rate can be expected in patients with single-vessel CAD, and an 80% survival rate after PCI can be achieved in those with multivessel CAD. In a 5-year follow-up study of patients treated with the TAXUS stent, target vessel revascularization during the first year was driven by target lesion revascularization, and target vessel revascularization after 1 year involved similar numbers of target lesion and non-target lesion revascularization events, primarily as a result of progression of atherosclerotic disease.¹¹¹ The annualized hazard ratio for non-target lesion revascularization and other major adverse events (including death, MI, and stent thrombosis) was relatively constant beyond 1 year and not significantly different between paclitaxel-eluting stents and BMSs.¹¹¹

Outcomes Benchmarking and Procedural Volumes

Along with CABG, PCI ranks among the most studied of all procedures in the United States. National structured outcomes registries, such as the National Heart, Lung and Blood Institute (NHLBI) Dynamic Registry¹¹²⁻¹¹⁶ and the ACC National Cardiovascular Data Repository (NCDR), have been examined.^{11,117-120} The NCDR CathPCI registry also provides contemporary risk-adjusted outcomes benchmarked to hundreds of participating institutions. Participants in such national, regional, or statewide outcomes-reporting initiatives can compare their risk-adjusted clinical outcomes with those at institutions with similar patient mix and size. The detailed nature of these data sets, in which the data collected span the range of patient clinical characteristics, lesion descriptors, and device-level information, provides centers with a comprehensive comparison of their practice patterns and outcomes with those at peer institutions. of hospitals in the United States participate in the NCDR CathPCI registry. Participation in a prospective quality assessment and outcomes registry is recommended for centers performing PCI.

Guidelines recommend that physicians undergo a 3-year comprehensive cardiac training program with 12 months of training in diagnostic catheterization, during which the trainee performs 300 diagnostic catheterizations, including 200 as the primary operator. Interventional training requires a fourth year of training, including more than 250 interventional procedures, a level that is also required for physicians to be eligible for the American Board of Internal Medicine certifying examination in interventional cardiology.

The guidelines favor performance of PCI by higher-volume operators, defined as those performing more than 75 procedures per year at high-volume centers (those in which more than 400 procedures are performed each year). These recommendations are based on the dated observations that higher-volume operators have lower adverse event rates than do lower-volume operators.^{121,122} In one analysis of 1338 PCIs performed in the United States and Canada, operators with fewer than 100 cases per year had higher rates of 30-day death, MI, or target vessel revascularization (13.2% versus 8.7%, $P = 0.18$) and large MI (7.7% versus 3.3%, $P = 0.06$) than did those with 100 or more cases per year.¹²² However, a more contemporary analysis of primary PCI found no relationship between hospital PCI volume and mortality in hospitals participating in a quality improvement initiative.¹²³

Although PCI has traditionally been performed at centers that offer on-site surgical backup, more recent analyses have shown that PCI for STEMI and elective PCI can be performed safely, provided that PCI is performed by high-volume operators with minimal institutional volume requirements.^{11,124-126} Off-site PCI is best suited for underserved areas that are geographically far removed from major centers.¹²⁷

Institutions must have a system for quality measurement and improvement that includes valid peer review. The guidelines recommend that quality assessment reviews take into consideration risk adjustment, statistical power, and national benchmark statistics. They should also include tabulation of adverse event rates for comparison with benchmark values, as well as case review of complicated procedures and some uncomplicated procedures.

FUTURE PERSPECTIVES

After three decades of rapid growth and dissemination of coronary interventional techniques and the associated dramatic refinement in the devices used for revascularization, many challenges still remain for the percutaneous treatment of CAD. Ongoing large-scale multicenter randomized trials will assess the safety and efficacy of PCI with DESs in patients with unprotected left main coronary artery stenosis. Additional technologies are currently in clinical testing for the treatment of complex bifurcation stenosis with dedicated bifurcation stent systems. Better techniques to treat chronic total occlusions are being developed.

DES design is continually evolving in an attempt to optimize effective early endothelialization of the stented segment without sacrificing the long-term benefits of DESs in reducing target lesion revascularization. Theoretically, advances in stent, polymer, and drug design could lead to improvements in restenosis and thrombosis rates, which in turn may reduce rates of MI and even death (Fig. 55-9).¹²⁸ Of course, this concept would need to be tested prospectively in adequately powered trials of sufficient duration, but it could lead to reexamination of the relative merits of PCI versus medical therapy or CABG in a variety of settings.

FIGURE 55-9 Theoretical framework by which second-generation DESs might decrease the risk for MI and cardiovascular death in comparison to BMSs, even though first-generation DESs did not. (From Bhatt DL: Examination of new drug-eluting stents—top of the class! *Lancet* 380:1453, 2012.)

Determination of the optimal duration of antiplatelet therapy following DES deployment requires further study. Bioabsorbable stents, produced from bioerodible polymers or magnesium alloys, show promise as a mechanism of providing short-term scaffolding to prevent abrupt closure of the vessel while leaving nothing permanent in the vessel wall after 6 months, thereby potentially reducing the risk for stent thrombosis.

Early investigations of myocardial regeneration following acute MI by percutaneous delivery of autologous stem cell or progenitor cell lines have generated great interest in the potential of such therapies to improve myocardial recovery (see Chapter 30), although much more clinical data are needed. Continued refinement of ventricular support devices offers hope for myocardial recovery in the setting of severe myocardial dysfunction.

GUIDELINES

Percutaneous Coronary Intervention

Laura Mauri and Deepak L. Bhatt

The American College of Cardiology/American Heart Association (ACC/AHA) published their initial guidelines for the performance of percutaneous coronary intervention (PCI) in 2001 and have since provided a series of focused updates that revised selected recommendations based on the ever-expanding clinical evidence base and evolving practice patterns.¹⁻³ In aggregate, these guidelines have provided clinicians with the tools required to enhance clinical decision making for patients undergoing percutaneous revascularization.

As with other ACC/AHA guidelines, they use the standard ACC/AHA classification system for indications:

Class I: Conditions for which there is evidence and/or general agreement that the test is useful and effective

Class II: Conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness or efficacy of performing the test

Class IIa: Weight of evidence or opinion is in favor of usefulness or efficacy

Class IIb: Usefulness or efficacy is less well established by evidence/opinion

Class III: Conditions for which there is evidence and/or general agreement that the test is not useful or effective and in some cases may be harmful

Three levels are used to rate the evidence on which recommendations have been based:

Level A: Recommendations are derived from data from multiple randomized clinical trials

Level B: Recommendations are derived from a single randomized trial or nonrandomized studies

Level C: Recommendations are based on the consensus opinion of experts

CLINICAL FEATURES

Guidelines relevant to the use of PCI to improve survival over that achieved with medical therapy (**Table 55G-1**) and to improve symptoms in patients with significant anatomic or physiologic coronary artery stenoses (**Table 55G-2**) and ST-elevation myocardial infarction (STEMI) (**Table 55G-3**) are provided.

TABLE 55G-1 ACC/AHA Recommendations for Percutaneous Coronary Intervention to Improve Survival Over That Achieved with Medical Therapy²

ANATOMIC SETTING	CLASS	RECOMMENDATION	LOE
Unprotected left main or complex CAD	Class I	Heart team approach recommended	C
	Class IIa	Calculation of STS and SYNTAX scores	B
Unprotected left main	Class IIa	PCI for SIHD when both are present: anatomic conditions associated with a low risk for procedural complications, e.g., a low SYNTAX score of ≤ 22 , ostial or trunk left main CAD, and clinical characteristics that predict a significantly increased risk for adverse surgical outcomes, such as an STS-predicted risk for operative mortality $\geq 5\%$	C
	Class IIa	PCI for UA/NSTEMI if not a CABG candidate	B
	Class IIa	PCI for STEMI when distal coronary flow is TIMI flow grade < 3 and PCI can be performed more rapidly and safely than CABG	C
	Class IIb	PCI for SIHD when both of the following are present: anatomic conditions associated with a low to intermediate risk for procedural complications and an intermediate to high likelihood of good long-term outcome, e.g. a low to intermediate SYNTAX score of < 33 , bifurcation left main CAD, and clinical characteristics that predict an increased risk for adverse surgical outcomes, such as moderate to severe COPD and disability from previous stroke or previous cardiac surgery, as well as an STS-predicted risk for operative mortality $> 2\%$	B
3-vessel disease	Class IIb	PCI of uncertain benefit relative to CABG	B

CABG = coronary artery bypass graft; CAD = coronary artery disease; COPD = chronic obstructive pulmonary disease; LOE = level of evidence; NSTEMI = non-ST-segment elevation myocardial infarction; SIHD = stable ischemic heart disease; STEMI = ST-segment elevation myocardial infarction; STS = Society of Thoracic Surgeons; TIMI = Thrombolysis in Myocardial Infarction; UA = unstable angina.

TABLE 55G-2 ACC/AHA Recommendations for Percutaneous Coronary Intervention to Improve Symptoms in Patients with Significant Anatomic or Physiologic Coronary Artery Stenosis²

ANATOMIC SETTING	CLASS	RECOMMENDATION	LOE
≥ 1 significant stenosis and unacceptable angina despite GDMT	Class I	PCI or CABG	A
≥ 1 significant stenosis and unacceptable angina in patients in whom GDMT cannot be implemented	Class IIa	PCI or CABG	C
Previous CABG with ≥ 1 significant stenosis associated with ischemia and unacceptable angina despite GDMT	Class IIa	PCI	C
Complex 3-vessel CAD (e.g., SYNTAX score > 22) and a good candidate for CABG	Class IIa	CABG preferred over PCI	B

GDMT = guideline-directed medical therapy; LOE = level of evidence.

TABLE 55G-3 ACC/AHA Recommendations for Percutaneous Coronary Intervention in Patients with ST-Segment Elevation Myocardial Infarction³

INDICATION	CLASS	RECOMMENDATION	LOE
Primary PCI	Class I	STEMI symptoms within 12 hours	A
		Severe heart failure or cardiogenic shock	B
		Contraindications to fibrinolytic therapy with ischemic symptoms <12 hours	B
	Class IIa Class III Harm	Clinical and/or ECG evidence of ongoing ischemia between 12 and 24 hours after symptom onset	B
		Non-infarct-related artery PCI at the time of primary PCI in patients without hemodynamic compromise	C
Delayed or elective PCI	Class IIa	Clinical evidence of fibrinolytic failure or infarct artery reocclusion	B
		Ischemia on noninvasive testing	B
	Class IIb	Hemodynamically significant stenosis in a patent infarct artery >24 hours after STEMI	B
	Class III	Totally occluded infarct artery >24 hours after STEMI in a hemodynamically stable asymptomatic patient	B
	No benefit	without evidence of severe ischemia	

ECG = electrocardiographic; LOE = level of evidence.

TABLE 55G-4 ACC/AHA Recommendations for Antiplatelet and Antithrombin Pharmacotherapy During Percutaneous Coronary Intervention³

INDICATION	CLASS	RECOMMENDATION	LOE
Aspirin	Class I	Patients already taking daily long-term ASA therapy should take 81-325 mg of ASA before PCI is performed	B
		Patients not taking ASA therapy should be given nonenteric ASA, 325 mg, before PCI	B
P2Y ₁₂ inhibitors Clopidogrel/prasugrel/ ticagrelor	Class I	A loading dose of clopidogrel, generally 600 mg, should be administered before or when PCI is performed	A
		Clopidogrel: a 600-mg loading dose is recommended	B
		Prasugrel:	B
		Generally not recommended in patients >75 years of age	
		Consideration of using a lower maintenance dose in patients weighing <60 kg suggested by the FDA	
	Class III	Ticagrelor: Issues of patient compliance may be especially important because it is given twice daily Prasugrel is contraindicated in patients with previous TIA/CVA	B B
Glycoprotein IIb/IIIa inhibitors	Class I	If no clopidogrel pretreatment and UA/NSTEMI with high-risk features	A
	Class IIa	If no clopidogrel pretreatment and STEMI, most appropriate with large anterior MI and/or large thrombus burden	A
		If no clopidogrel pretreatment and SIHD	B
	Class IIa	If clopidogrel pretreatment and STEMI, most appropriate with large anterior MI and/or large thrombus burden	C
	Class IIa	If clopidogrel pretreatment and UA/NSTEMI with high-risk features	B
	Class IIb Class III	If clopidogrel pretreatment and SIHD Percutaneous coronary intervention laboratory administration of GPI for STEMI	B B
Unfractionated heparin	Class I	Dosing based on whether GPI was given	C
Bivalirudin	Class I	The lower bleeding rates associated with bivalirudin are mitigated when used with a GPI	B
Enoxaparin	Class I	An additional dose of 0.3 mg/kg of IV enoxaparin should be administered at the time of PCI to patients who have received <2 therapeutic SC doses (e.g., 1 mg/kg) or received the last SC enoxaparin dose 8-12 hours before PCI	B
	Class IIb	Recommendations for IV enoxaparin during PCI apply to patients who have not received previous antithrombin therapy or who have received "upstream" SC enoxaparin therapy for UA/NSTEMI	B
	Class III Harm	Patients treated with SC enoxaparin within 12 hours of PCI should not receive additional treatment with UFH during PCI	B
Fondaparinux	Class III Harm	PCI should not be performed with fondaparinux as the sole antithrombin agent in patients treated with upstream fondaparinux. An additional anticoagulant with anti-IIa activity should be administered	C

ASA = aspirin; CVA = cerebrovascular accident; FDA = U.S. Food and Drug Administration; GPI = glycoprotein IIb/IIIa inhibitor; LOE = level of evidence; MI = myocardial infarction; NSTEMI = non-ST-segment elevation MI; TIA = transient ischemic attack; SIHD = stable ischemic heart disease; STEMI = ST-segment elevation myocardial infarction; UA = unstable angina; UFH = unfractionated heparin.

ADJUNCTIVE PHARMACOTHERAPY

The expanding number of antiplatelet and antithrombin agents available for use during PCI has provided clinicians with a number of competing therapeutic options. Guidelines for antiplatelet therapy and antithrombin therapy during PCI have been provided (Table 55G-4). Guidelines for antiplatelet therapy after PCI have also been provided (Table 55G-5). In addition, there is increasing awareness that providing optimal medical therapy following PCI is mandatory,

including secondary risk factor modifications such as lipid-lowering therapy (see Chapter 42).

APPROPRIATENESS CRITERIA FOR PERCUTANEOUS CORONARY INTERVENTION

An ongoing challenge for the application of guidelines to clinical practice is to construct expert opinion for the appropriateness of revascularization based on integration of the clinical findings,

TABLE 55G-5 ACC/AHA Postprocedure Recommendations for Antiplatelet Therapy in Patients Undergoing Percutaneous Coronary Intervention³

INDICATION	CLASS	RECOMMENDATION	LOE
Aspirin	Class I	After PCI, use of aspirin should be continued indefinitely	A
	Class IIa	After PCI, it is reasonable to use ASA, 81 mg/day, in preference to higher maintenance doses	B
P2Y ₁₂ inhibitors: STEMI and unstable angina/NSTEMI	Class I	In patients receiving a stent during PCI for ACS, P2Y ₁₂ inhibitor therapy should be given for at least 12 months. Options include clopidogrel, 75 mg/day; prasugrel, 10 mg/day; or ticagrelor, 90 mg twice daily	B
	Class I	In patients receiving a DES during PCI for a non-ACS indication, clopidogrel, 75 mg/day, should be given for at least 12 months if not at high risk for bleeding	B
		In patients receiving a BMS during PCI for a non-ACS indication, clopidogrel, 75 mg/day, should be given for a minimum of 1 month and ideally up to 12 months (unless the patient is at increased risk for bleeding, in which case it should be given for a minimum of 2 weeks)	C
		PPIs should be used in patients with a history of previous GI bleeding who require DAPT	C
	Class IIa	If the risk for morbidity from bleeding outweighs the anticipated benefit afforded by a recommended duration of P2Y ₁₂ inhibitor therapy after stent implantation, earlier discontinuation (e.g., <12 months) of P2Y ₁₂ inhibitor therapy is reasonable	C
	Class IIb	Use of PPIs is reasonable in patients with an increased risk for GI bleeding who require DAPT	C
		Continuation of clopidogrel, prasugrel, or ticagrelor beyond 12 months may be considered in patients undergoing placement of a DES	C
	Class III no benefit	Routine use of a PPI is not recommended for patients at low risk for GI bleeding	C

ACS = acute coronary syndrome; ASA = aspirin; BMS = bare metal stent; DAPT = dual antiplatelet therapy; DES = drug-eluting stent; GI = gastrointestinal; LOE = level of evidence; NSTEMI = non-ST-segment myocardial infarction; PPI = proton pump inhibitor; STEMI = ST-segment elevated myocardial infarction.

TABLE 55G-6 Noninvasive Risk Stratification

High Risk (>3% Annual Mortality Rate)

1. Severe resting LV dysfunction (LVEF <35%)
2. High-risk treadmill score (score less than or equal to -11)
3. Severe exercise-induced LV dysfunction (exercise LVEF <35%)
4. Stress-induced large perfusion defect (particularly if anterior)
5. Stress-induced multiple perfusion defects of moderate size
6. Large, fixed perfusion defect with LV dilation or increased lung uptake (thallium-201)
7. Stress-induced moderate perfusion defect with LV dilation or increased lung uptake (thallium-201)
8. Echocardiographic wall motion abnormality (involving >2 segments) developing with low-dose dobutamine (≤10 mg/kg/min) or at a low heart rate (<120 beats/min)
9. Stress echocardiographic evidence of extensive ischemia

Intermediate Risk (1-3% Annual Mortality Rate)

1. Mild to moderate resting LV dysfunction (LVEF = 35-49%)
2. Intermediate-risk treadmill score (greater than -11 to <5)
3. Stress-induced moderate perfusion defect without LV dilation or increased lung uptake (thallium-201)
4. Limited stress echocardiographic ischemia with a wall motion abnormality only at higher doses of dobutamine involving ≤2 segments

Low Risk (<1% Annual Mortality Rate)

1. Low-risk treadmill score (≥5)
2. Normal or small myocardial perfusion defect at rest or with stress
3. Normal stress echocardiographic wall motion, no change, or limited resting wall motion abnormalities during stress

LV = left ventricular; LVEF = LV ejection fraction.

Modified from Patel MR, Dehmer GJ, Hirshfeld JW, et al: ACCF/SCAI/STS/AATS/AHA/ASNC 2009 appropriateness criteria for coronary revascularization: A report of the American College of Cardiology Foundation Appropriateness Criteria Task Force, Society for Cardiovascular Angiography and Interventions, Society of Thoracic Surgeons, American Association for Thoracic Surgery, American Heart Association, and the American Society of Nuclear Cardiology: Endorsed by the American Society of Echocardiography, the Heart Failure Society of America, and the Society of Cardiovascular Computed Tomography. *J Am Coll Cardiol* 53:530, 2009.

noninvasive testing, coronary anatomy, and the intensiveness of medical therapy. Appropriateness criteria for revascularization based on a consensus opinion of interventionalists, cardiac surgeons, and noninvasive cardiologists were published in 2009⁴ and updated in 2012.⁵ Risk stratification for cardiac events was established (Table 55G-6), and a series of clinical scenarios were graded on a scale of 1 to 9 based on the following appropriateness definitions:

Score of 7 to 9: Appropriate (A) when the expected benefits, in terms of survival or health outcomes (symptoms, functional status, and/or quality of life), exceed the expected negative consequences of the procedure.

Score of 4 to 6: Uncertain (U) for the indication provided, which means that coronary revascularization may be acceptable and may be a reasonable approach for the indication but with uncertainty

implying that more research and/or patient information is needed to further classify the indication.

Score of 1 to 3: Inappropriate (I) for the indication provided, which means that coronary revascularization is not generally acceptable and not a reasonable approach for the indication and is unlikely to improve the patient's health outcomes or survival.

The appropriateness for revascularization in various manifestations of acute coronary syndromes (ACSs) is listed in Table 55G-7. In general, the guidelines support a very prominent role for revascularization in patients with ACSs. The criteria for stable coronary artery disease are based on the extent of disease in the coronary arteries, the complexity of the coronary anatomy, the severity of angina, the degree of ischemia, and the extent of antianginal medical therapy (Tables 55G-8 through 55G-10). These key

TABLE 55G-7 Appropriate Use Criteria for Revascularization in Patients with Acute Coronary Syndromes^{4,5}

INDICATION		APPROPRIATE USE SCORE (1-9)
1	<ul style="list-style-type: none"> STEMI ≤12 hours from onset of symptoms Revascularization of the culprit artery 	A (9)
2	<ul style="list-style-type: none"> STEMI Onset of symptoms within the previous 12-24 hours Severe HF, persistent ischemic symptoms, or hemodynamic or electrical instability present 	A (9)
3	<ul style="list-style-type: none"> STEMI >12 hours from symptom onset Asymptomatic; no hemodynamic instability and no electrical instability 	I (3)
4	<ul style="list-style-type: none"> STEMI with presumed successful treatment by fibrinolysis Evidence of HF, recurrent ischemia, or unstable ventricular arrhythmias present One-vessel CAD, presumed to be the culprit artery 	A (9)
5	<ul style="list-style-type: none"> STEMI with presumed successful treatment by fibrinolysis Asymptomatic; no HF, no recurrent ischemic symptoms, or no unstable ventricular arrhythmias Normal LVEF One-vessel CAD presumed to be the culprit artery 	U (5)
6	<ul style="list-style-type: none"> STEMI with presumed successful treatment by fibrinolysis Asymptomatic; no HF, no recurrent ischemic symptoms, or no unstable ventricular arrhythmias at evaluation Depressed LVEF Three-vessel CAD Elective/semielective revascularization 	A (8)
7	<ul style="list-style-type: none"> STEMI with successful treatment of the culprit artery by primary PCI or fibrinolysis Asymptomatic; no HF, no evidence of recurrent or provokable ischemia, and no unstable ventricular arrhythmias during the index hospitalization Normal LVEF Revascularization of a non-infarct-related artery during the index hospitalization 	I (2)
8	<ul style="list-style-type: none"> STEMI or NSTEMI and successful PCI of the culprit artery during the index hospitalization Symptoms of recurrent myocardial ischemia and/or high-risk findings on noninvasive stress testing performed after the index hospitalization Revascularization of 1 or more additional coronary arteries 	A (8)
9	<ul style="list-style-type: none"> UA/NSTEMI and low-risk features associated with short-term risk for death or nonfatal MI Revascularization of the presumed culprit artery 	U (6)
10	<ul style="list-style-type: none"> UA/NSTEMI and intermediate-risk features associated with short-term risk for death or nonfatal MI Revascularization of the presumed culprit artery 	A (8)
11	<ul style="list-style-type: none"> UA/NSTEMI and high-risk features associated with short-term risk for death or nonfatal MI Revascularization of the presumed culprit artery 	A (9)
12	<ul style="list-style-type: none"> UA/NSTEMI and high-risk features associated with short-term risk for death or nonfatal MI Revascularization of multiple coronary arteries when the culprit artery cannot clearly be determined 	A (9)
13	<ul style="list-style-type: none"> Patients with acute MI (STEMI or NSTEMI) Evidence of cardiogenic shock Revascularization of 1 or more coronary arteries 	A (8)

A = appropriate; CAD = coronary artery disease; HF = heart failure; I = inappropriate; LVEF = left ventricular ejection fraction; MI = myocardial infarction; NSTEMI = non-ST-segment elevation MI; STEMI = ST-segment elevated myocardial infarction; U = uncertain; UA = unstable angina.

factors must all be weighed before deciding on the appropriateness of revascularization. Patients who have previously undergone coronary artery bypass grafting (CABG) and require repeated revascularization merit special consideration because the risks associated with repeated bypass surgery are higher than with the initial surgery. In patients who have previously undergone CABG, the guidelines recommend revascularization for severe angina (Canadian class III or IV), especially with large areas of ischemia and when medical therapy has already been maximized. The appropriate mode of revascularization by PCI or CABG for various anatomic subsets incorporates the burden of coronary artery disease and the presence of total occlusion (which may be measured by the SYNTAX score⁶) into the decision making. Importantly, in the focused update of 2012, two revisions resulted in a higher appropriateness rating for PCI than in the initial appropriateness criteria published in 2009, based largely on the positive results of the SYNTAX (Synergy Between PCI with TAXUS and Cardiac Surgery) randomized trial in these subgroups of patients.⁷ Three-vessel

disease is categorized as appropriate for PCI when there are three focal stenoses or a low SYNTAX score but categorized as uncertain in appropriateness for PCI if multiple diffuse lesions or an intermediate to high SYNTAX score is present (Table 55G-11).⁵ Isolated left main stenosis and left main disease with a low burden of CAD are classified as uncertain appropriateness for treatment by PCI. The terms Appropriate, Uncertain, and Inappropriate have been recently updated and replaced with the terms Appropriate, May Be Appropriate, and Rarely Appropriate.

GUIDELINES FOR TRAINING

The guidelines recommend that physicians undergo a 3-year comprehensive cardiac training program before dedicated interventional training in an accredited program. Interventional training requires a fourth year of training, including more than 250 interventional procedures, a level that is required for physicians to be eligible for the American Board of Internal Medicine certifying examination in

REFERENCES, 1276

Arguably, transcatheter management of structural heart disease dates back more than 30 years with the first successful percutaneous closure of atrial septal defects (ASDs) and the advent of balloon valvuloplasty. However, in the last decade the broad field of structural heart intervention has undergone its most rapid development with improvements in image guidance, the availability of specialized skills, and the completion of pivotal clinical trials of novel devices. This chapter reviews transcatheter interventional therapy for structural heart disease in adults. Although the focus is primarily on acquired conditions, some conditions that are not acquired typically become apparent in adulthood and are also briefly reviewed.

OCCCLUSION OF CARDIAC DEFECTS

Patent Foramen Ovale

A probe-patent foramen ovale (PFO) is present in 20% to 25% of the adult population. In utero the foramen ovale allows blood to flow across the atrial septum, thereby circumventing the pulmonary circulation (see Chapter 62). This communication normally closes shortly after birth as pulmonary blood flow increases and the flaplike septum primum is forced against the septum secundum. Functional closure is usually followed by permanent fusion of the two flaps. Traditionally considered an innocent remnant of the fetal circulation, a PFO is now assessed in living adults via echocardiographic techniques during the evaluation of those in whom right-to-left shunting may be a central pathophysiologic feature of such diverse conditions as cryptogenic stroke (paradoxical embolism), migraine (shunting of vasoactive substances or microemboli), decompression illness (nitrogen air embolism), and various states characterized by systemic hypoxemia such as platypnea-orthodeoxia (shunting of deoxygenated blood while recumbent).

Paradoxical embolism through a PFO with an arterial embolic event has been the major area of relevance to interventions for structural heart disease with the development of PFO closure devices and delivery systems. The largest target population studied has been patients with cryptogenic stroke, in whom the frequency of finding a PFO is often double that in the general population and in whom the optimal secondary prevention strategy is not well defined. Evidence supporting paradoxical embolism causing a stroke is primarily indirect and presumptive because it is rare to visualize an embolism traversing the PFO. This produces the challenge of separating those with an incidental PFO and an unrelated cryptogenic stroke from those with an enabling PFO and the resultant stroke. Moving beyond the suggestive data showing an association of the presence of a PFO with cryptogenic stroke has been more challenging than originally expected, and this holds even more in the case of migraine. PFO device closure trials have been used to not only assess the safety and

efficacy of a device-based strategy but also as a test of the underlying hypothesis of cause and effect. Many single-center studies have been published, most have been retrospective, but all have been observational, often with historical controls. The results of these reports have been summarized in meta-analyses supporting the superiority of device closure, frequently with concomitant antiplatelet therapy, versus medical therapy alone.^{1,2} Randomized trials have been desperately needed but are difficult to perform, and to date only one migraine trial and three stroke trials have been reported without definitive results proving superiority of device therapy with a high level of certainty.^{3,5} Defining the target patients most likely to benefit from PFO closure continues to be the central challenge in the setting of low recurrent ischemic stroke rates with medical therapy alone.

Transcatheter PFO closure is performed via femoral venous access, and placement of the device is guided by fluoroscopy and ultrasound, either intracardiac or transesophageal (Fig. 56-1). A delivery sheath is placed across the PFO, and the most commonly used devices are deployed in a sequential fashion with a disc on the left atrial side followed by the right atrial disc. The discs are joined to produce a cuff link type of closure mechanism. Devices and delivery systems use different materials, have a few sizes, and are generally straightforward to use. The completeness of closure is a function of the initial mechanical closure followed by device endothelialization over subsequent months. The diversity of PFO anatomy necessitates selection of the device that will be a best fit for the anatomy and yield complete closure. Complete closure occurs in up to 80%, and in an additional 10% to 15% the residual right-to-left shunting appears to be trivial. In the United States no PFO closure devices have been approved by the Food and Drug Administration, and consequently off-label use of ASD closure devices is widespread.

The frequency of complications is low and varies with the device used. Vascular complications are rare. Intraprocedural complications such as perforation resulting in tamponade, air embolism, device embolization, and stroke are all rare events in experienced hands, with rates of less than 1%. Subsequent atrial arrhythmias may occur in 3% to 5% but are generally transient, although the rate of development of atrial fibrillation has been 5% to 6% with some devices, which have also been associated with thrombus formation on the device. Both complications can lead to stroke. Late cardiac perforation has been reported with some devices but appears to be rare.

Current indications for PFO closure remain controversial because of the lack of clarity from randomized trials despite the widespread belief that PFO closure is reasonable in some patients. There is broader agreement when medical therapy has failed to prevent recurrent strokes that are presumed to be due to paradoxical embolism. Some clinicians believe that the low risk associated with PFO closure, the positive evidence from observational trials, the hazards related to long-term anticoagulation, and identification of high-risk features in patients such as atrial septal aneurysm justify the selective use of device closure of PFOs as a reasonable adjunct for secondary prevention, especially in younger patients with cryptogenic stroke. The role

FIGURE 56-1 Intracardiac echocardiographic guidance of PFO closure in a subject participating in the RESPECT trial using the Amplatzer PFO occluder. **A**, The thin septum primum is held apart from the thick septum primum (arrows) by a guidewire. **B**, The deployed device functions as a cuff link holding the two tissue flaps together. **C**, A fluoroscopic image from a left anterior oblique cranial projection shows the deployed device placed properly. LA = left atrium; RA = right atrium.

of PFO closure for migraine remains investigative.⁶ The role of PFO closure for hypoxemia is based on direct evidence of substantial shunting in the individual patient.

Atrial Septal Defect

Secundum ASDs are the most common type of ASD (see Chapter 62). Assessment and characterization are straightforward, and the role of transcatheter closure is well established.⁷ In adults, ASDs may be detected incidentally or during the evaluation of dyspnea, fatigue, palpitations, or paradoxical embolism. Echocardiographic evaluation (see Chapter 14) is directed toward characterization of the impact of the volume overload (right ventricular and right atrial enlargement), assessment of the position and margins of the defect, evaluation for pulmonary hypertension, and detection of associated defects, including anomalous pulmonary venous return.

Complex defects such as ostium primum and sinus venosus ASDs are more complex and generally require surgical closure, as do very large (diameter >36 mm) secundum ASDs and those with inadequate rim tissue (see Fig. 14-90). Defects associated with pulmonary hypertension and advanced pulmonary vascular disease require in-depth and multidisciplinary assessment of the pulmonary hypertension and its potential for reversibility, the safety of ASD closure, and the use of concomitant medical therapy for the pulmonary hypertension.

Two devices are widely used for closure of secundum ASDs in North America: the Amplatzer atrial septal occluder (ASO) and the Gore Helex device. ASD occlusion is generally performed via femoral venous access with transesophageal or intracardiac echocardiographic guidance to size the defect, place the device, and evaluate the result (see Figs. 14-87 through 14-91). Complex anatomic subsets may require specialized techniques and equipment, multiple devices, and advanced imaging for planning and guidance, especially three-dimensional transesophageal echocardiography (Fig. 56-2).

ASD closure generally results in a reduction in dilation of the right-sided chambers, as well as improvement in symptoms. However,

FIGURE 56-2 Closure of a secundum ASD with three-dimensional transesophageal guidance during deployment of an Amplatzer ASO occluder. **A**, The defect is seen from the left atrial side. **B**, Delivery catheter across the defect with the device still inside. **C**, The deployed left atrial disc is exposed by unsheathing. **D**, The left atrial disc is now opposed to the septum and occluding the defect, and the right atrial disc is deployed (not illustrated).

benefit varies with the degree of chamber enlargement and age. Complications are rare but can include device embolization, particularly when defects are large, complex, or associated with deficient rims and suboptimal device fixation. Atrial fibrillation may occur early as a consequence of atrial manipulation or later as a consequence of chronic atrial dilation and injury. Device thrombosis may occur, but rarely. A particular concern with the Amplatzer ASO device is late erosion involving the roof of the atria or aortic root and

subsequently resulting in cardiac perforation and life-threatening cardiac tamponade. The frequency of this serious complication appears to be 0.1% to 0.3%. Risk factors include an oversized implant and a deficient aortic rim. Although erosions generally take place within the first year after implantation, late erosion is rare but may occur.⁸

Postprocedural care usually includes a transthoracic echocardiogram to assess the final clinical and structural result, 6 months of antiplatelet therapy, and antibiotic prophylaxis for procedures associated with bacteremia.

Ventricular Septal Defect

Acquired ventricular septal defects (VSDs) in adults are relatively rare. They can occur as a consequence of trauma or cardiac surgery. However, the great majority occur in association with acute myocardial infarction. Rupture of the interventricular septum complicates approximately 0.2% of acute infarctions, most often related to a large area of necrotic, weakened transmural myocardium. Patients are usually first seen 2 to 7 days following an acute myocardial infarction—beyond the window of reperfusion strategies—with recurrent chest pain and new-onset heart failure.

Defects that develop in this setting are often irregular, serpiginous, sometimes multiple, and prone to further expansion with time or manipulation. Cardiogenic shock is the norm, and mortality exceeds 90% if left untreated. Even in patients undergoing emergency surgical patch exclusion of a ruptured ventricular septum, mortality ranges from 30% to 60%. Percutaneous closure has been accomplished with various devices, most often with a specialized Amplatzer occluder. An experienced operator can generally implant an occluder safely, but efficacy is variable and mortality remains very high because of myocardial dysfunction and residual leaks. Successful closure is most likely to occur when the defect is small, away from the free ventricular walls and mitral attachments, and chronic. The choice between surgical and percutaneous options must take into account assessment of surgical risk, implications of the defect's location for surgical exclusion versus percutaneous occlusion, and the need for additional revascularization or valve procedures.

Left Atrial Appendage

Atrial fibrillation is the most common cause of cardioembolic stroke, with an annual stroke rate of 2% to 5% (see Chapter 38). Oral anticoagulants can reduce this risk for stroke but are associated with a significant risk for bleeding. It is well established that most thromboemboli associated with atrial fibrillation originate in the left atrial appendage (LAA). In recognition of this, surgical exclusion of the LAA is relatively common in high-risk patients undergoing cardiac surgery for other indications in the hope of reducing the risk for subsequent cardioembolic stroke. More recently, the feasibility of percutaneous LAA exclusion has been demonstrated with a number of percutaneous devices. Currently, two endovascular LAA exclusion systems are in widespread clinical use. The Watchman device (Boston Scientific Corp., Natick, Mass) and the Amplatzer Cardiac Plug (St. Jude Medical, Inc., St. Paul, Minn) both incorporate a self-expanding nitinol frame, barbs for fixation, and a polyester fabric cover (Fig. 56-3, Video 56-1). Both require detailed assessment of LAA anatomy and exclusion of thrombi with transesophageal echocardiography. Transseptal access to the left atrium is achieved from the femoral vein, following which the device is implanted under fluoroscopic and transesophageal echocardiographic guidance. Both devices can be repositioned. An alternative percutaneous approach using an epicardial suture to ligate and exclude the LAA has recently become available. The efficacy and relative safety of the Lariat device (SentreHEART, Inc., Redwood City, Calif) have been established, although direct comparison to anticoagulation is lacking.⁹

The bulk of experience and data to date have been with the Watchman device. In the randomized PROTECT-AF trial, LAA exclusion appeared to be noninferior to warfarin therapy for prevention of stroke.¹⁰ However, short-term complications, notably pericardial effusions related to transseptal access in this early experience, were increased, and late safety and efficacy were not established. It is generally accepted that LAA exclusion can reduce the risk for stroke in patients with atrial fibrillation. Currently, LAA occlusion appears to be a reasonable option in patients who are intolerant of or have failed treatment with oral anticoagulants.

A transseptal balloon catheter is placed in the appendage. A percutaneous pericardial catheter is positioned with the aid of magnets. A snare is used to occlude the appendage.

FIGURE 56-4 Three-dimensional transesophageal echocardiogram of a mitral mechanical bileaflet valve following transapical paravalvular leak closure. An Amplatzer vascular plug has been implanted at approximately the 2 o'clock position relative to the valve sewing ring.

Paravalvular Regurgitation

Paravalvular regurgitation after valve replacement may occur as a consequence of an incomplete seal between the inflow sewing ring of the prosthetic valve and the annulus. Annular calcification, infection, and technical factors may predispose to dehiscence of the surgical suture and result in a localized paravalvular leak. Most small leaks occurring very early after surgery seal spontaneously and do not require treatment. However, when paravalvular regurgitation is severe, congestive heart failure may result. Hemolysis may develop because of the high-velocity left ventricular-to-left atrial jets associated with mitral leaks, even when relatively small. The great majority of symptomatic leaks occur in association with mitral valves and, much more rarely, in association with aortic valves.

Reoperation for such leaks is accompanied by significant morbidity and mortality, as well as an increased likelihood of recurrent leaks. Medical management may be the best option for many such patients, but percutaneous closure might be an option in carefully selected patients (Fig. 56-4). To date, the role of percutaneous

closure has been limited by technical difficulty and modest efficacy. However, results have improved with recent advances in imaging (particularly three-dimensional transesophageal echocardiography), technique (steerable transseptal catheters, apical access), and improved closure devices.¹¹ A large number of devices have been used to occlude paravalvular leaks. Most of this experience has been with devices not specifically designed for this purpose but rather for closure of a septal defect (Video 56-2), vascular anomalies, or a patent ductus arteriosus. Complications, although infrequent, include device embolization, interference with mechanical leaflets, and pericardial effusions. The potential for partial closure of a mitral paravalvular leak to worsen hemolysis is well documented, but it may resolve as tissue ingrowth occurs. Newer devices specifically designed for the typical crescentic shape of paravalvular defects and the use of multiple smaller devices may offer more effective sealing. Regardless of which device is used, the defect must first be imaged and cannulated under transesophageal echocardiographic and fluoroscopic guidance. Aortic and some mitral leaks can be cannulated retrogradely from the aorta. However, most mitral leaks require a transseptal puncture to access the left atrium (Video 56-3) or direct needle puncture of the left ventricle either percutaneously or through a minithoracotomy.

AORTIC VALVE INTERVENTIONS (see Chapter 63)

Aortic Balloon Valvuloplasty

Percutaneous aortic balloon valvuloplasty for degenerative aortic stenosis was initially described in 1985. Its initial enthusiasm was tempered when it became apparent that its benefit was modest and not durable. Complications were frequent, including stroke, severe aortic regurgitation, and access site injury, although more recent reports have documented a marked reduction in complications, presumably because of improved equipment and technique. Currently, it does appear that aortic valvuloplasty may offer modest clinical benefit. In the largest series to date, valve area increased less than 0.4 cm² in 77% of patients.

Unfortunately, the clinical benefit of aortic balloon valvuloplasty is not durable. Restenosis, with loss of symptomatic benefit, occurs in approximately 50% of patients by 6 months and in most patients by 1 year. Pathologic data have shown that balloon valvuloplasty improves leaflet mobility by fracturing calcified nodules and creating cleavage planes within the collagenous stroma. Restenosis appears to occur as a result of granulation tissue, fibrosis, and active osteoblast-mediated calcification. Procedural improvements do not appear to have increased this durability. Repeated valvuloplasty has been proposed as a palliative approach, although the durability and degree of benefit appear to be progressively reduced.

The possibilities for further improvements in this procedure appear to be limited. Recently, it has been demonstrated that external beam irradiation early following aortic balloon valvuloplasty may reduce the rate of restenosis. However, the potential for benefit appears to be modest, and this approach has not found favor. More aggressive valvuloplasty using specially constructed valvuloplasty balloons, such as noncompliant balloons (Loma Vista Medical, Inc., Burlingame, Calif) and balloons with “cutting, scoring, or focused force” metallic elements, have been used, although benefit has yet to be demonstrated (Angioscore, Inc., Fremont, Calif).

Current American College of Cardiology/American Heart Association guidelines¹² recognize the possibility that aortic balloon valvuloplasty may have a limited therapeutic role. Valvuloplasty is considered a class

IIb therapeutic option as a bridge to surgical or transcatheter aortic valve replacement in severely symptomatic or hemodynamically unstable patients in whom the risk associated with valve replacement is high. Most recently, balloon valvuloplasty has found an expanded role as a major component of a transcatheter aortic valve implantation strategy.

Aortic Valve Implantation

Catheter implantation of aortic valves was first accomplished in 2002.¹³ This procedure has come to be known as transcatheter aortic valve replacement or implantation (TAVR or TAVI). The initial experience involved transvenous access with transseptal catheterization to gain access to the left side of the heart. Although feasible, this method was rapidly supplanted by transarterial access from the femoral artery. The initial catheter systems were large in diameter and required surgical access to the femoral artery; however, with marked reductions in delivery catheter dimensions and improved percutaneous access site technique, suture-based “preclosure” is increasingly being used.

Although transarterial femoral access has become the preferred, default access for TAVR, a number of alternative access routes have been used widely. Open access to the left ventricle through a small lateral thoracotomy (transapical), the axillary artery (transaxillary or transsubclavian), or the ascending aorta (direct aortic) all have their advocates.¹⁴

Currently, two aortic valve systems are widely available.

The SAPIEN valve (Edwards Lifesciences, Irvine, Calif) incorporates a balloon-expandable stainless steel stent frame within which are sewn bovine pericardial leaflets (Video 56-4). A synthetic fabric sealing cuff surrounds the inflow of the valve to prevent paravalvular leaks. This is the valve evaluated in the PARTNER trial,^{15,16} and it is currently approved for clinical use in the United States. Its successor, the SAPIEN XT valve, is constructed of a chromium alloy frame and has various minor improvements and one major advantage in that it is compatible with newer low-profile delivery catheters. The next-generation SAPIEN 3 valve is compatible with even lower-profile delivery systems and has various improvements that facilitate accurate positioning and improve paravalvular sealing (Fig. 56-5, Video 56-5).

The CoreValve ReValving System (Medtronic, Inc., Minneapolis) incorporates a self-expanding nitinol alloy frame within which are sewn porcine pericardial leaflets. A pericardial sealing cuff surrounds the inflow of the valve (Fig. 56-6, Video 56-6). The self-expanding frame is constrained within a delivery catheter. As the valve is released from the delivery catheter, the frame expands to assume its predetermined shape. The lower portion of the frame with its sealing cuff is positioned within the aortic annulus and displaces the native leaflets. The middle portion contains the pericardial valve. The upper portion extends above the coronaries to anchor and align the prosthesis within the ascending aorta.

A large number of new transcatheter aortic valves are currently in early clinical evaluation (Fig. 56-7).¹⁷ These valves typically offer appealing features that facilitate positioning, repositioning, fixation,

FIGURE 56-5 The SAPIEN transcatheter heart valves (Edwards Lifesciences, Inc.) incorporate a balloon-expandable frame, bovine pericardial leaflets, and a fabric sealing cuff.

**VIDEO 56-2**

Left atrial appendage closure. Femoral venous puncture allowed access to the right atrium, followed by a transseptal puncture that allowed access to the left atrium. An Amplatzer cardiac plug was then implanted into the left atrial appendage. Occlusion of the left atrial appendage may reduce the risk of embolic stroke.

VIDEO 56-3

Fluoroscopic images of valve implantation in failed mitral valve. A small intercostal incision facilitates needle puncture of the left ventricular apex and introduction of a sheath into the left ventricle. A transcatheter balloon-expandable valve is then deployed inside a degenerated and regurgitant mitral surgical bioprosthetic valve, resulting in relatively normal mitral valve function.

VIDEO 56-4

Mitral valvuloplasty. Femoral venous puncture followed by transseptal puncture allows access to the left atrium and mitral valve. A rheumatic, stenotic mitral valve is then dilated with a self-seating Inoue valvuloplasty balloon.

VIDEO 56-5

Paravalvular leak closure. A mitral mechanical surgical prosthesis has a paraprosthetic leak with regurgitation resulting in hemolysis. Following transseptal puncture, the paravalvular defect is crossed and an Amplatzer occluder implanted, resulting in a reduced paravalvular regurgitation.

VIDEO 56-6

Percutaneous aortic valve implantation using a 14F sheath. Transcatheter valve implantation. Minimally invasive implantation of a Sapien 3 valve in an awake patient with next-day discharge.

sealing, or a reduction in delivery catheter diameter. However, previous experience with surgical valves has shown that some enhancements may introduce the possibility of new mechanisms of failure, and therefore extensive evaluation will be necessary before widespread application.

The hemodynamic characteristics of current transcatheter valves compare favorably with surgical valves. Transvalvular regurgitation

is rare, but paravalvular regurgitation is common, although for the most part it is relatively mild and well tolerated. Clinical hemolysis has not been evident. Clinically significant paravalvular leaks may sometimes occur because of poor sealing as a consequence of undersizing or poor alignment of the prosthesis. If severe, such leaks may require postimplant dilation, implantation of a second overlapping valve, or rarely, surgical replacement. Recently, there has been concern that even mild or moderate leaks may be associated with reduced late survival.¹⁸ Although a cause-and-effect relationship has not been proved, there is consequently increased interest in minimizing paravalvular leaks.

Arterial injury has been the major cause of morbidity and mortality complicating TAVR. As a result, detailed iliofemoral angiography and/or multislice computed tomography has become a routine component of the screening process, and a major focus of ongoing development has involved reducing the profile of delivery systems. Atrioventricular block may occur because of compression of the conduction system as it passes through the periaortic septum. Predisposing factors may include preexisting conduction abnormalities, oversizing of the prosthesis, and extension of the prosthesis into the outflow tract. Permanent pacemakers are required in 5% to 30% of patients, a frequency that varies with the specific type of valve implanted and local practice. Coronary obstruction may occur rarely when a bulky native leaflet is displaced over the left main coronary ostium (<1%), and stroke may occur because of embolization from the native valve or aortic arch (1% to 4%). Important in the future evaluation of transcatheter valve therapy has been the recent development by the Valve Academic Research Consortium of standardized outcomes definitions that allow valid comparisons between studies.¹⁹

Current transcatheter valves appear to be sufficiently durable to provide benefit in the mostly elderly patients with comorbid conditions who are currently considered candidates. Accelerated wear

FIGURE 56-6 The CoreValve device (Medtronic, Inc.) incorporates a self-expanding frame that is anchored at both the annulus and the supracoronary aorta. The middle portion contains a porcine pericardial valve.

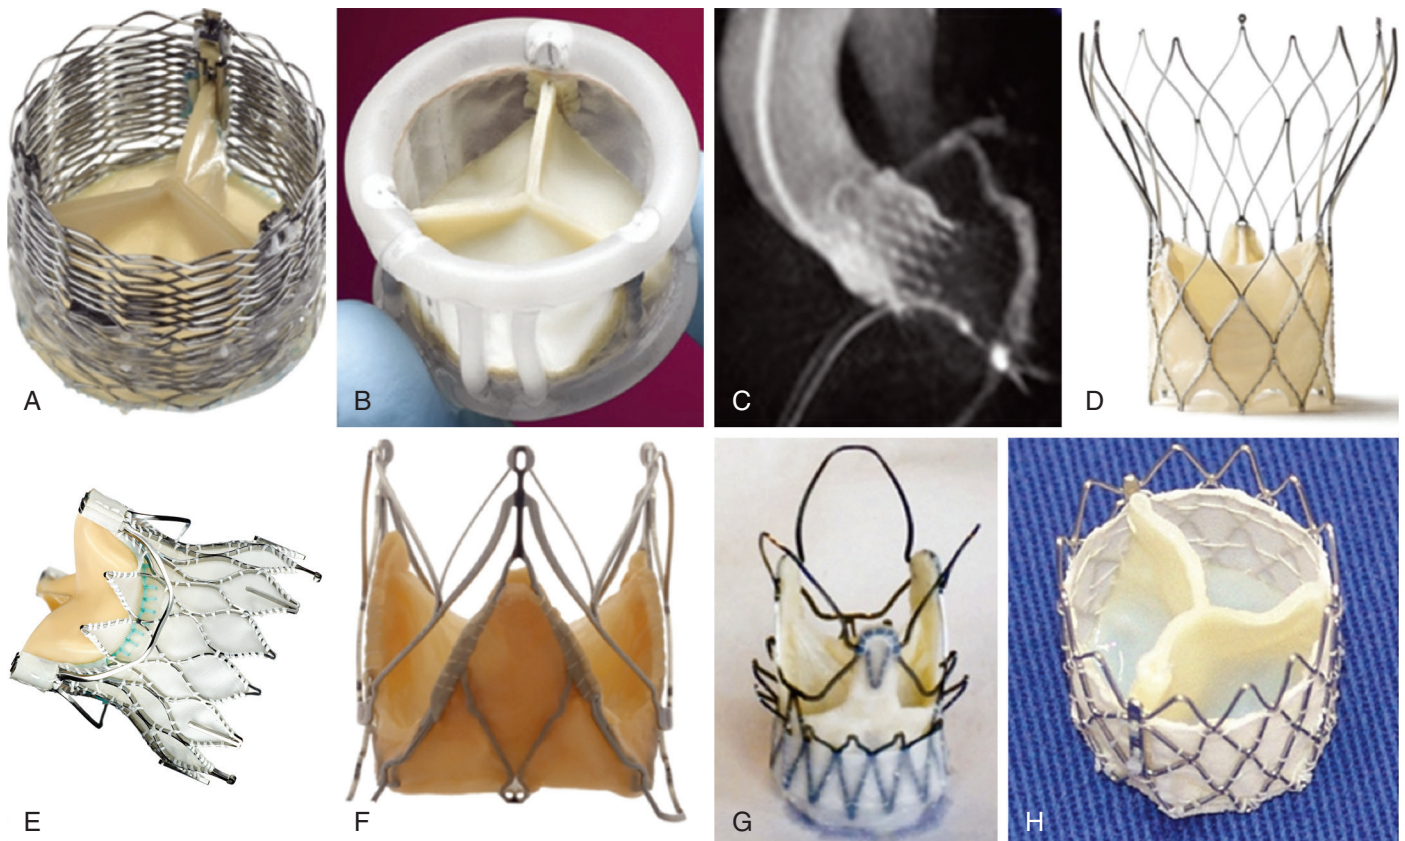

FIGURE 56-7 Newer valves currently in trials include **A**, the Lotus (Boston Scientific Corp.); **B**, Direct Flow (Direct Flow Medical, Inc., Santa Rosa, Calif); **C**, CENTERA (Edwards Lifesciences, Inc.); **D**, Portico (St. Jude Medical, Inc.); **E**, Engager (Medtronic, Inc.); **F**, JenaClip (JenaValve Technology, Inc., Wilmington, Del); **G**, Acurate (Symetis, Inc., Ecublens, Switzerland); and **H**, Inovare valve (Braile Biomédica, Inc., Sao Jose do Rio Preto, Brazil).

testing has demonstrated *in vitro* durability of longer than 10 years, but midterm structural valve failure has not been rare, although clinical follow-up remains limited beyond 3 to 5 years. Whether such durability is sufficient for younger patients with the potential for longevity remains to be determined. However, the feasibility of transcatheter valve-in-valve implants in failing surgical and transcatheter bioprosthetic prostheses has been demonstrated, and this strategy may be appealing when eventual transcatheter valve failure occurs.^{20,21}

Multiple single and multicenter high-risk registries have documented survival rates comparable to those anticipated with surgical valve replacement.^{14,16-18} This, in conjunction with less morbidity, has been appealing. The large randomized North American PARTNER trial evaluated the first-generation, large-profile Edwards SAPIEN valve. In patients considered to be at too high risk to undergo surgery (PARTNER 1B, inoperable), TAVR was dramatically superior to medical management, with an absolute reduction in 1-year mortality of 20%¹⁵ that increased to 36% at 2 years.²² In patients considered high risk but acceptable for surgery (PARTNER 1A, high risk), transarterial TAVR was noninferior to surgery at 1 and 2 years but was associated with less morbidity.¹⁸

Surgical aortic valve replacement remains the current standard of care for symptomatic aortic stenosis because of a large body of favorable experience (see Chapter 63). In the absence of long experience and additional randomized comparisons, current guidelines recommend TAVR only for patients in whom the risk for morbidity or mortality with surgery is high.^{12,23} A Society of Thoracic Surgeons predicted risk of mortality (STS-PROM) exceeding 10% (www.sts.org) has been widely used to define “high risk.” However, such predictive models are severely limited when it comes to certain comorbid conditions such as ascending aortic calcification, multivalve disease, hostile chest, very severe lung disease, liver disease, and frailty. Moreover, the reduced morbidity associated with a transcatheter procedure may be more important to many older patients than the potential for reduced mortality. Frequently, the opinion of an experienced heart team is the best estimate of risk.¹⁴

MITRAL VALVE INTERVENTION

Mitral Balloon Valvuloplasty

Percutaneous valvuloplasty using inflatable balloon catheters was first developed as a therapeutic option for congenital pulmonary and aortic valvular stenosis in the early 1980s. Several techniques of mitral balloon valvuloplasty were developed that incorporate single or double cylindrical balloons and even a mechanical dilator. Currently, mitral valvuloplasty is performed via transseptal access to the left atrium. The self-centering, dumbbell-shaped, Inoue balloon is most often used (Video 56-7).

Mitral balloon valvuloplasty has become a mainstay in the management of rheumatic mitral stenosis (see Chapter 63), with efficacy comparable to that achieved with closed or open surgical commissurotomy.²³ Although rheumatic valvular disease is increasingly rare in developed countries, it remains common in less developed countries, where mitral balloon valvuloplasty is a common procedure. Balloon valvuloplasty can be very effective in the setting of rheumatic commissural fusion. However, the procedure is relatively ineffective in the absence of commissural fusion, as in degenerative, calcific mitral stenosis or in congenital or prosthetic stenosis, in which the risk for severe regurgitation generally contraindicates this procedure.

Patient selection for mitral valvuloplasty is based largely on echocardiographic assessment of the mitral valve apparatus.¹¹ The echocardiographic Wilkins score (see Table 14-10) attempts to consider the anatomic characteristics of the leaflets, commissures, and chordal apparatus. This system assigns a point value from 1 to 4 for each of the following: (1) leaflet calcification, (2) leaflet mobility, (3) leaflet thickness, and (4) subvalvular apparatus degeneration. A score less than 8 suggests a favorable response to valvuloplasty, whereas a score of 9 to 16 suggests that surgical replacement may be needed. Even in the presence of a low score, adverse baseline factors to be considered include increasing severity of regurgitation, advanced age, previous commissurotomy, absence of commissural fusion, and the presence of commissural calcification.

A favorable result is evidenced by a reduction in the mean transmitral gradient from more than 10 to less than 5 mm Hg, without the development of severe mitral regurgitation. Complications, although uncommon, may include pericardial tamponade as a consequence of transseptal puncture, stroke secondary to thromboembolism, and severe mitral regurgitation. Relative contraindications to valvuloplasty include left atrial thrombus and unfavorable valve anatomy, which might predispose to mitral regurgitation. Multiple lines of evidence, including randomized comparisons with open surgical commissurotomy, have demonstrated that the procedure can be performed with a relatively low rate of complications and durable benefit.²⁴ In young to middle-aged patients with optimal anatomy, the rate of freedom from restenosis has been reported to be approximately 85% at 5 years, comparable to that for open surgical commissurotomy. When restenosis does occur, redilation may often be feasible, with surgical valve replacement generally being the alternative.

MitraClip

Transcatheter technologies have developed in parallel with advancements in understanding of the pathophysiology, echocardiographic assessment, and anatomic characterization of mitral regurgitation.²⁵ A number of approaches to transcatheter management of mitral valve regurgitation have proved unsuccessful. In contrast, the MitraClip device has been demonstrated to be successful in multiple clinical trials, including the randomized EVEREST trial.^{26,27} The MitraClip is now an approved device in the United States for patients with degenerative forms of mitral regurgitation in whom the risk associated with surgical valve repair or replacement is high, and the procedure also is widely available in many other countries. Creation of a mechanical bridge between the midportion of the anterior and posterior mitral valve leaflets is the fundamental therapeutic mechanism, hence use of the term “edge-to-edge repair” as initially described in the surgical Alfieri technique. As a result the regurgitant orifice is reduced, with often only a mild degree of residual regurgitant flow, and subsequent chamber remodeling, improved functional class, and reduced rates of hospitalization for heart failure have been demonstrated.

Optimal patient selection for the MitraClip procedure is key to achieving optimal results. Patients with excessive thickening of leaflets, extensive degeneration or flail of leaflet tissue, or other technical challenges for delivery of the MitraClip must be identified via echocardiographic assessment. The target patient population is generally those in whom mitral valve surgery would be high risk.

The MitraClip procedure is usually performed with the patient under general anesthesia to facilitate transesophageal guidance. Transseptal access facilitates placement of a deflectable guide catheter into the left atrium (Fig. 56-8). A steerable delivery catheter is then used to manipulate a mechanical clip across the mitral valve that can grasp the two mitral leaflets. If a good functional result is not obtained, the clip can be released and repositioned or an additional clip can be introduced.

Patients are generally hemodynamically stable during the procedure, with complications occurring relatively infrequently and major complications (such as stroke, emergency surgery, death, and perforation) being relatively rare. Atrial arrhythmias, access-related bleeding, and residual ASDs may occur but are usually easily managed. Chordal injury, clip detachment, mitral stenosis, and clinical failure may occur, although most patients remain candidates for the alternative of surgical repair.

Other Mitral Valve Procedures

A number of investigational mitral valve repair procedures attempt to replicate surgical repair procedures such as annuloplasty and chordal repair.²⁸ Similarly, a number of groups are currently developing transcatheter valve implantation procedures. However, the mitral valve is a complex three-dimensional structure, which in addition to a host of other concerns, makes fixation and sealing problematic. With the exception of MitraClip, experience with transcatheter mitral valve repair and replacement remains preliminary. In contrast, transseptal and transapical transcatheter valve-in-valve implants within failed surgical mitral bioprostheses have proved to be reproducible

**VIDEO 56-7**

Pulmonary percutaneous valve implantation. A stenotic homograft valve incorporated into a pulmonary conduit has been stented open. A balloon-expandable valve was then deployed within the previously implanted conduit stent.

procedures with early outcomes that appear favorable in comparison to mitral valve reoperation.¹⁹ Early experience with transcatheter valve-in-ring implants in patients who have previously undergone surgical annuloplasty remains preliminary.²⁰

PULMONARY VALVE

The use of surgically implanted valved conduits to reconstruct the right ventricular outflow tract in patients with congenital heart disease has allowed most of these patients to survive to adulthood (see Chapter 62). However, bioprosthetic valve failure invariably occurs and may require multiple open heart operations over a lifetime. Balloon dilation or stenting of stenosed pulmonary bioprostheses may allow temporary palliation but does not provide a durable solution.

Percutaneous transcatheter implantation of stented valves in pulmonary valved conduits was first reported in 2000, following which clinical uptake has been relatively rapid. The bulk of this experience has been with the Melody valve (Medtronic, Inc.), which incorporates a bovine jugular venous valve sutured inside a balloon-expandable platinum-iridium stent (Fig. 56-9, Video 56-8). To date, clinical outcomes have been, for the most part, very good with a very small risk for conduit rupture, left main coronary compression, and conversion to surgery. There has been concern with regard to the low radial

strength and propensity for stent strut fracture with this particular stent frame. However, this has largely been allayed by the practice of routine stent implantation before valve implantation and by demonstration of the feasibility of implanting a second transcatheter valve when necessary. Recently, the bovine pericardial SAPIEN aortic valve, with a stronger stainless steel balloon-expandable frame, has been used in the pulmonary position.

LEFT VENTRICULAR MODIFICATION

Septal Ablation

Septal ablation in patients with obstructive hypertrophic cardiomyopathy (HCM) has joined medical management and surgical techniques as a standard option for the treatment of symptomatic patients (see Chapter 66). Centers specializing in this technique have demonstrated sustained symptomatic improvement and reduction of gradients.

The procedure is performed similar to routine coronary interventions and involves cannulation of the left anterior descending coronary artery. A large septal perforator supplying a portion of the proximal interventricular septum is identified and cannulated with an over-the-wire angioplasty balloon.^{29,30} Contrast material is injected through the wire port of the occlusive balloon catheter to evaluate a potential area of tissue ablation. If a suitable area of myocardium is identified, a small quantity (1 to 2 mL) of absolute alcohol is injected to induce the signs and symptoms of a localized myocardial infarction (Fig. 56-10).

Echocardiographic and catheter assessment of gradients and a temporary pacemaker for potential heart block are part of the procedure. An immediate reduction in the subaortic gradient is usually followed by a further gradient reduction over a period of months as the tissue edema resolves and scar formation and contraction occur. Major complications are rare but may include significant arrhythmias, left ventricular dysfunction, and perforation of the interventricular septum. Persistent heart block may occur and require pacemaker implantation in 10% to 20% of patients.

The role of septal ablation versus various surgical options remains controversial (see Chapter 66). Centers specializing in the treatment of HCM may have preferences based on local interventional and surgical expertise. Nevertheless, septal ablation needs to be incorporated into a programmatic approach involving comprehensive assessment of the cause of the symptoms, risk for sudden cardiac death, and usefulness of family genetic and echocardiographic screening.

FUTURE PERSPECTIVES

Transcatheter management of structural heart disease in adults has undergone rapid advances over the past decade. Most intracardiac defects are now managed percutaneously. Aortic valvuloplasty plays an important adjunctive role in the management of aortic stenosis, and TAVI is rapidly becoming routine. Valve-in-valve implants appear likely to play an important role in managing degenerative bioprosthetic valves (Videos 56-9 56-10, and 56-11). Mitral valvuloplasty is first-line therapy for many patients with rheumatic mitral stenosis, and edge-to-edge repair is now an option for patients with mitral regurgitation. LAA exclusion is a widely accepted therapeutic option in patients at risk for thromboembolism. These therapies can be expected to evolve rapidly, as can other new, unexpected, and sophisticated approaches to the transcatheter management of structural heart disease.

The aorta, the largest artery in the body, is divided anatomically into thoracic and abdominal components. The thoracic aorta is subdivided into the ascending, arch, and descending segments, and the abdominal aorta, into the suprarenal and infrarenal segments. The ascending aorta has two distinct portions. The *aortic root* begins at the aortic valve and extends to the sinotubular junction. The aortic root supports the bases of the three aortic valve leaflets, which bulge outward into the sinuses of Valsalva during systole. The origins of the right and left coronary arteries arise from the sinuses of Valsalva. The upper portion of the ascending aorta begins at the sinotubular junction and rises to join the aortic arch. The proximal portion of the ascending aorta lies within the pericardial cavity, anterior to the pulmonary artery bifurcation. The aortic arch gives rise to the innominate artery, the left common carotid artery, and the left subclavian artery. The descending thoracic aorta begins distal to the left subclavian artery. The point at which the aortic arch joins the descending aorta, denoted the *aortic isthmus*, is marked by the location of the ligamentum arteriosum. The aortic isthmus is vulnerable to deceleration trauma because at this site the ascending aorta and arch become relatively fixed to the thoracic cage. The descending aorta gives rise to posterior paired intercostal arteries at each level of the spine. Distally, the thoracic aorta passes through the diaphragm and becomes the abdominal aorta.

The abdominal aorta gives rise to the celiac artery and the superior mesenteric artery anteriorly, followed by the posterolateral origins of the right and left renal arteries. This segment of the aorta is called the suprarenal or visceral segment. The infrarenal aorta lies anterior to the lumbar spine, where paired lumbar artery branches arise posteriorly. The aorta ends by bifurcation into common iliac arteries.

Microscopic Structure. The aortic wall includes three layers: (1) the innermost *tunica intima*, (2) the musculoelastic *tunica media*, and (3) the outer fibrous *tunica adventitia*. The intima, lined by endothelial cells, is demarcated from the media by the internal elastic lamina. The media is characterized by concentric layers of elastic fibers alternating with vascular smooth muscle cells (SMCs), with each layer of elastin and SMCs constituting a "lamellar unit" of the medial structure. In addition to SMCs, the aortic media normally contains a small number of fibroblasts, mast cells, and the extracellular matrix, including collagen fibers, proteoglycans, and glycosaminoglycans. The media gives the aorta its circumferential resilience (elasticity), which is necessary to resist hemodynamic stress. The outer portion of the aortic media is delineated from the adventitia by the external elastic lamina. The adventitia is composed of collagen fibers, fibroblasts, small nerves,

and blood vessels. The adventitial collagen fibers ultimately govern the tensile strength of the aortic wall.

The ascending aorta normally contains approximately 55 to 60 elastic lamellae, with a gradual decrease in the number of elastic lamellae down the length of the aorta to approximately 26 at the aortic bifurcation. Oxygen and nutrients are supplied to the aortic wall by simple diffusion from the lumen, at least in segments of the aorta that contain up to approximately 29 elastic lamellae. In the proximal aortic segments, additional nutrients are supplied by an independent network of microvessels, the *vasa vasorum*, which extends from the adventitia to the outer layers of the elastic media. The outer third of the aortic media in the thoracic aorta contains many *vasa vasorum*, but the infrarenal aorta normally lacks an independent microvascular supply.

The compliance of the aortic wall under normal conditions results from reversible extension of the elastic lamellar units in the media. At mechanical strain levels that exceed the extensile capacity of the medial elastic fibers, aortic tensile strength becomes dependent on the collagen fiber meshwork of the media and adventitia. Although not functionally significant under normal circumstances or in systemic hypertension, the dependence on adventitial collagen in accommodating greater hemodynamic stress is an important feature of abdominal aortic aneurysms (AAAs), for which estimates of wall tension within the dilated segment may be orders of magnitude higher than in a normal aorta. In AAAs, collagen fibers reorganize to accommodate higher degrees of tensile stress. Evidence shows that an active process characterized by a marked increase in collagen production accompanies aneurysmal dilation. Surgical experience has shown that much of the inner arterial wall (endothelium and tunica media) can be removed, as is done during endarterectomy, without resulting in aneurysmal dilation.

Physiology

The aorta transmits pulsatile arterial blood pressure to all points in the arterial tree, a function that depends on its properties as an elastic conduit. The biomechanical properties of the aorta, including resilience to cyclical deformation, are attributable to elastin and collagen in the media and adventitia. The aortic wall pressure-diameter relationship is nonlinear; a more distensible component is demonstrated at lower pressures and a stiffer component at higher pressures, with the transition from distensible to stiff behavior occurring at pressures higher than 80 mm Hg.

The pressure-diameter curve of the aorta becomes less steep with increasing age (i.e., the aorta stiffens and aortic diameter increases). Potential explanations for this change include (1) an increase in the collagen-to-elastin ratio because of a decrease in elastin and an increase in collagen, (2) changes in the aortic wall with progressively disordered medial elastic fibers and lamellae displaying thinning and fragmentation, (3) an increase in aortic wall thickness with deposition of collagen and other extracellular matrix macromolecules and

calcification of elastic fibers, and (4) arteriosclerotic changes leading to wall stiffening.

Evaluation of the Aorta

The only location in which the aorta can normally be palpated is in the midabdominal region, where in some individuals (depending on body habitus) it may be detected by deep palpation adjacent to the spine. Plain radiography is insensitive in evaluating the thoracic and abdominal aorta, but much more diagnostic detail regarding the aorta can be obtained with imaging modalities such as ultrasound (including echocardiography), computed tomography (CT), magnetic resonance imaging (MRI), and less frequently, aortography.

AORTIC ANEURYSMS

The term *aortic aneurysm* refers to a pathologic segment of aortic dilation that has a propensity to expand and rupture. The extent of aortic dilation required to be considered aneurysmal is debated, but one criterion is an increase in diameter of at least 50% greater than expected for the same aortic segment in unaffected individuals of the same age and sex. Aortic aneurysms are usually described in terms of their size, location, morphology, and cause. Size criteria are

focused on cross-sectional diameter as measured on imaging studies. Aortic aneurysms are either *fusiform* or *saccular*. Fusiform aneurysms, the more common type, are symmetrically dilated with involvement of the entire aortic circumference. Saccular aneurysms exhibit localized dilation involving only a portion of the aortic wall circumference, where they appear as a focal outpouching. These lesions represent “true” aneurysms in that the aortic wall is intact but dilated and all layers of the aortic structure are involved. In contrast, pseudoaneurysms (false aneurysms) represent lesions in which bleeding has occurred through the aortic wall and resulted in a contained periaortic hematoma in continuity with the aortic lumen. Pseudoaneurysms may result from trauma or contained rupture of an aortic aneurysm, dissection, or penetrating ulcer.

Abdominal Aortic Aneurysms

AAAs are defined by an increase in size of the abdominal aorta to greater than 3.0 cm in diameter.¹ AAAs occur in 3% to 9% of men older than 50 years and are the most common form of aortic aneurysms. Most AAAs (>80%) arise in the infrarenal aorta (Fig. 57-1), but up to 10% may involve the pararenal or visceral aorta and some extend into the thoracoabdominal segment. AAAs are approximately five times more prevalent in men than in women, and their incidence is strongly associated with age, with most occurring in those older than 60

FIGURE 57-1 AAA before and after EVAR. **A**, CT axial image demonstrating a 5.3-cm infrarenal AAA. **B**, Preoperative CT scan with sagittal reconstructions demonstrating the 5.3-cm AAA and the anatomy of the aorta and iliac vessels. **C**, Postoperative cross-sectional CT images 1 year after EVAR demonstrating a decrease in AAA size and no endoleak. **D**, Postoperative three-dimensional reconstruction of the AAA 1 year after EVAR on the same patient. (Courtesy Dr. Gregorio Sicard, Washington University School of Medicine.)

years.² AAAs are also strongly associated with cigarette smoking, with current and former smokers having a fivefold increase in risk in comparison to nonsmokers. Additional risk factors include emphysema, hypertension, and hyperlipidemia. Up to 20% of patients with AAAs describe a family history of aortic aneurysms, thus suggesting the contribution of a heritable component.

Pathogenesis

AAA formation is associated with chronic aortic wall inflammation, increased local expression of proteinases, and degradation of structural connective tissue proteins. Aneurysmal dilation and rupture result from mechanical failure of medial elastin and adventitial collagen. Inflammatory cells commonly infiltrate the aortic wall. In some cases, patients with "inflammatory AAAs" exhibit extension of this process to the periaortic retroperitoneal tissues. Matrix-degrading enzymes released by inflammatory cells lead to medial degeneration and play a role in dilation and rupture.

Inflammatory cells may enter the media in response to signals elaborated by medial SMCs as a result of hemodynamic stress, ischemia, autoimmune processes, or extension of intimal atherosclerosis. Proinflammatory cytokines, such as tumor necrosis factor- α , interleukin-1 β , interleukin-6, and interferon- γ , may play a role. Although a response to both foreign antigens and microbial infection has been postulated in the development of AAAs, evidence shows that the chronic inflammation in aneurysm tissue also exhibits features of an autoimmune response. Destruction of medial elastin and a marked decrease in the concentration of elastin are consistent features of AAAs. Experimental studies have demonstrated that damage to the elastic lamellae leads to aneurysmal dilation, and elastolytic proteinases may play a critical role. The tensile strength of the aortic wall results principally from interstitial collagen, and AAAs are generally associated with increased collagen content. Enzymes that initiate cleavage of interstitial collagen may contribute to rapid aneurysm expansion and rupture.

The most prominent elastin- and collagen-degrading enzymes produced in human AAA tissue are matrix metalloproteinases (MMPs). MMPs degrade a broad range of matrix proteins, with four MMPs exhibiting activity against elastin (MMP-2, MMP-7, MMP-9, and MMP-12). At least three MMPs initiate the degradation of intact fibrillar collagen (MMP-1, MMP-8, and MMP-13). MMP activity is closely regulated at the level of gene transcription, as well as by proteases and reactive oxygen species that mediate extracellular activation and by interaction with secreted tissue inhibitors of metalloproteinases (TIMPs) and other proteinase scavengers. MMP-9 appears to be especially important in human and experimental AAAs; MMP-9 expression is markedly elevated in aneurysm tissue, and AAAs are suppressed in mice lacking expression of MMP-9. Moreover, treatment of experimental animals with tetracyclines and other MMP inhibitors has consistently suppressed aneurysm development. Other experimental interventions found to suppress AAAs, such as treatment with statins and anti-inflammatory agents, have decreased MMP-9 in aortic tissue. These observations have led to the potential use of doxycycline and other MMP inhibitors to suppress the progression of aneurysms in patients with small AAAs.³

The natural history of AAAs involves a balance between degradative and reparative processes. Because vascular SMCs normally produce elastin and collagen during aortic development and SMCs predominate within the elastic media, they may mediate repair of connective tissue within AAAs. Depletion of medial SMCs characterizes AAAs. Mechanisms underlying the loss of SMCs in AAAs include apoptosis, which may be initiated by medial ischemia, signaling molecules, or cellular immune responses. Medial SMC ischemia has been considered another factor involved in AAA degeneration because in the absence of vasa vasorum, the nutrient supply to the media depends on diffusion from the aortic lumen—which may be jeopardized by intimal thickening and atherosclerotic plaque.

Clinical Features

AAAs develop insidiously over a period of several years and rarely cause symptoms in the absence of distal thromboembolism, rapid

expansion, or rupture. Although large AAAs are at substantial risk of rupturing, the vast majority of AAAs are small. Most AAAs are detected by screening studies or as an incidental finding on imaging studies performed for another purpose.

Physical examination is insensitive in detecting AAAs, but abdominal palpation may reveal a pulsatile epigastric or periumbilical mass, particularly in thin patients with large aneurysms. Only 30% to 40% of AAAs are noted on physical examination, although aneurysms larger than 5 cm are detected in approximately 75% of patients, depending on body habitus.² The mural thrombi associated with AAAs may lead to thromboembolism, which may be the initial symptom in 2% to 5% of patients. Evaluation for AAA in patients with other vascular diseases is important—an AAA is present in up to 85% of patients with a femoral artery aneurysm and in approximately 60% of patients with a popliteal artery aneurysm.²

Diagnostic Imaging

Ultrasound/Computed Tomography/ Magnetic Resonance Imaging/Aortography

Abdominal ultrasound can detect AAAs with high accuracy and a sensitivity and specificity of almost 100% and is preferred over CT in screening for AAAs because it is inexpensive and noninvasive and avoids exposure to radiation and contrast agents.² Ultrasound also permits serial measurement of AAA size during the follow-up of patients with small AAAs. Because ultrasound-derived measurements of AAA diameter are less accurate than those obtained by CT or MRI, many recommend the use of ultrasound for follow-up of small AAAs and use CT or MRI for larger AAAs.

Abdominal CT is extremely accurate in both detection of AAAs and measurement of aneurysm diameter (Fig. 57-1). When combined with radiographic contrast enhancement, thin-slice techniques, and three-dimensional reconstructions with measurements obtained perpendicular to the center line of the aorta, CT angiography (CTA) is more accurate than ultrasound. CTA is especially useful in demonstrating the extent of aneurysmal disease; the relationship of the AAA to the renal, visceral, and iliac arteries; and patterns of mural thrombus, calcification, or coexisting occlusive atherosclerosis, which might influence AAA repair. Three-dimensional reconstructions, including multiplanar and volume-rendering techniques, enhance visualization of the AAA before endovascular aneurysm repair (EVAR) (Fig. 57-1). CT is also preferred for the assessment of AAA variants, such as inflammatory AAAs and mycotic aneurysms. Magnetic resonance angiography (MRA) also has high accuracy in detecting AAAs, measuring aneurysm diameter, and planning treatment. MRA avoids exposure to radiation and iodine-based contrast material. CT is the preferred imaging modality, however, for evaluation of AAAs in most institutions.

CTA has superseded aortography in the evaluation and management of AAAs. In patients undergoing EVAR, aortography is an initial step in the operative procedure. It is also used in subsequent interventions following AAA stent-graft repair, such as embolization of the lumbar or iliac artery branches. The characteristics of AAAs include an enlarged abdominal aortic segment marked by calcification. The aortic lumen may or may not appear enlarged because of the presence of mural thrombus.

Screening

Screening for AAAs with ultrasound, coupled with repair of AAAs above a given size threshold, has reduced AAA-related deaths.^{1,2} The overall incidence of screening-detected AAAs ranges from 1 per 1000 in adults younger than 60 years to 7 per 1000 in those in their mid-60s, but it may be as high as 10% in those with risk factors such as older age, male sex, smoking, family history, history of other aneurysms, hypertension, atherosclerotic diseases, and hypercholesterolemia. In asymptomatic U.S. veterans 50 to 79 years of age, 66% of AAAs identified by screening were smaller than 4.0 cm.² Aneurysm screening is associated with a 50% reduction in rupture and a 50% decrease in aneurysm-related mortality.^{1,2} Even though AAA screening is cost-effective in men 65 to 74 years of age, the cost-effectiveness of screening for AAAs in women remains controversial,¹ and routine screening

of women has not demonstrated a survival benefit.² Although women have a lower prevalence of AAAs than men do, AAAs occur about 10 years later in women, and rates of rupture and mortality from rupture are both higher. In 2005, the U.S. Preventive Services Task Force recommended a one-time ultrasound screening for AAAs in men 65 to 75 years of age with a history of smoking.^{1,2} The Society for Vascular Surgery recommends a one-time screening for AAAs in all men older than 65 years or as early as 55 years in men and women with a family history of AAAs.²

Genetics/Molecular Genetics

Several genetic disorders are associated with thoracic aortic aneurysms (TAAs), including Marfan syndrome (MFS), Loeys-Dietz syndrome (LDS), and vascular Ehlers-Danlos syndrome (vEDS), but less commonly with aneurysms of the abdominal aorta. (See the section [Thoracic Aortic Aneurysms](#).) Up to 20% of patients with an infrarenal AAA have a family history of AAAs, thus suggesting an inherited component. Several genetic variants appear to be linked with AAAs through analysis of single-nucleotide polymorphisms (SNPs) in large populations. A common sequence variant on chromosome 9p21 (rs10757278-G) is associated with a 31% increased risk for AAAs, as well as increased risk for intracranial aneurysms.⁴ Broader use of genome-wide screening may identify additional genetic factors associated with AAAs.

Natural History

The natural history of AAAs is gradual expansion over a period of years and eventual rupture. The average rate of expansion of AAAs between 3 and 5.5 cm ranges from 0.2 to 0.3 cm/year.¹ Not all AAAs follow a linear or consistent rate of expansion. Some patients may have stable AAAs that grow slowly for years, whereas others may have a stable AAA size for many years, followed by a sudden increase within a short period. Although the size of the aneurysm is most important in predicting rupture, size alone may not predict risk for rupture. Wall thickness, intraluminal thrombus thickness, and peak wall stress may all contribute.² The largest aneurysms have the highest risk for rupture, with the 1-year risk for rupture estimated to be 10% to 20% for AAAs 6.0 to 7.0 cm in diameter; 20% to 40% for AAAs 7.0 to 8.0 cm; and 30% to 50% for AAAs larger than 8.0 cm. The 5-year risk for rupture is approximately 5% for AAAs 3.0 to 4.0 cm in diameter, 10% to 20% for AAAs 4.0 to 5.5 cm, 30% to 40% for AAAs 5.5 to 6.0 cm, and higher than 80% for AAAs larger than 7.0 cm.²

Ruptured Abdominal Aortic Aneurysm

Symptoms directly attributable to AAAs are usually related to overt rupture of the aneurysm or rapid expansion and impending rupture. Rupture of AAAs into the peritoneal cavity results in acute hemorrhage, severe abdominal pain, and hypotension as a consequence of exsanguination. Rupture into the retroperitoneum may result in a temporarily contained periaortic hematoma, with severe abdominal or back pain that may radiate to the flank or groin. A tender pulsatile abdominal or flank mass is often present, along with hypotension and/or syncope. Approximately 30% to 50% of patients with ruptured AAAs die before hospitalization, and an additional 30% to 40% die after reaching a hospital but before treatment.² The operative mortality rate for open surgical repair (OSR) after AAA rupture is 40% to 50%, but it may be lower with EVAR.^{1,2} Hemodynamically stable patients with symptomatic but apparently unruptured AAAs should undergo CT to determine whether rupture has occurred. Because emergency repair entails a fourfold to fivefold higher mortality rate, in the absence of rupture, it may be prudent in certain cases to delay surgical repair for 4 to 24 hours until optimal conditions can be achieved, with the patient being closely monitored.²

Management

Surveillance/Medical Therapy

Patients with small AAAs can be observed safely with imaging surveillance and little risk for rupture. In general, AAA repair is reserved for asymptomatic aneurysms at least 5.0 to 5.5 cm in diameter.^{1,2} Symptomatic aneurysms and those with rapid growth (>1 cm/year)

require vascular surgical consultation.¹ In patients with AAAs larger than 4.5 cm, CT is preferred over ultrasound for more accurate measurement of AAA size. Surveillance of aneurysms until the diameter exceeds 5.5 cm is associated with a low rate of rupture (\approx 1% per year).² The Society of Vascular Surgery guidelines suggest the following surveillance strategy for AAAs of various size: 2.6 to 2.9 cm, imaging at 5 years; 3.0 to 3.4 cm, imaging every 3 years; 3.5 to 4.4 cm, imaging at 12 months; and 4.5 to 5.4 cm, imaging every 6 months.² Uncertainty exists regarding the ultimate therapy for AAAs between 4.5 and 5.4 cm, and recommendations must be individualized. Young, healthy patients—especially women—with AAAs between 5 and 5.4 cm may benefit from early repair.²

Several steps are recommended for patients with AAAs to help minimize the risk for expansion of the aneurysm and improve overall health. Smoking cessation is important inasmuch as strong evidence has linked ongoing tobacco use with more rapid rates of AAA expansion and rupture. Statin use can be recommended for almost all patients with AAAs based on the presence of coexisting atherosclerotic disease, and although randomized data are lacking, these medications may suppress AAA growth.³ Even though no available data have shown a benefit of angiotensin-converting enzyme (ACE) inhibitors on AAA expansion, they do demonstrate benefit in patients with vascular disease and should be considered.^{1,2} Currently, ACE inhibitors are being studied as part of two randomized controlled trials involving small AAAs. Patients with small AAAs should be encouraged to exercise regularly because moderate physical activity does not adversely influence the risk for rupture and may even limit the rate of AAA growth.

EXPERIMENTAL THERAPY. The potential use of pharmacologic therapies to suppress the growth rate of small AAAs and to reduce the need for surgical repair is of great interest.^{2,3} One of the earliest approaches suggested was the use of beta-adrenergic receptor-blocking agents (beta blockers) as a strategy to diminish hemodynamic stress. Although successful in animal models of AAAs, two large clinical trials demonstrated no benefit of propranolol treatment in patients with small AAAs.² Suppression of specific proteinases involved in degradation of the extracellular matrix is another approach. Treatment with doxycycline has suppressed or prevented AAAs in animal models in association with MMP inhibition, particularly inhibition of MMP-9.³ Doxycycline is well tolerated by patients with small AAAs, in whom it also appears to decrease MMP activity in aneurysmal aortic tissue and in the circulation. Further investigation is needed to determine whether doxycycline treatment can reduce the rate of AAA expansion. A third experimental approach is the use of ACE inhibitors or angiotensin receptor-blocking agents (ARBs), such as losartan, to modify the metabolism of connective tissue in the aortic wall. An increased risk for AAA rupture has been reported in individuals who stopped taking ACE inhibitors in the months before rupture.²

Surgery

The decision to undergo elective repair of an asymptomatic AAA depends on life expectancy and the estimated risk for rupture, balanced against the estimated risks associated with AAA repair. Factors significantly influencing operative morbidity and mortality include coronary artery disease (the leading cause of early and late mortality after AAA repair), chronic kidney disease, chronic obstructive pulmonary disease (COPD), and diabetes mellitus.² Thus further evaluation for these conditions is warranted before elective AAA repair, along with optimization of preoperative status.

Because many patients with AAAs have underlying coronary artery disease and because postoperative myocardial infarction (MI) poses a substantial risk for death or later cardiovascular events, special attention is directed toward coronary disease before elective AAA repair. Current guidelines state that in the absence of an active cardiac condition, further noninvasive testing is indicated only if it will change management. Some patients benefit from preoperative evaluation for coronary ischemia and treatment ([see Chapter 80](#)). Perioperative medical management to reduce cardiac risk in patients undergoing AAA repair may include appropriate administration of

beta blockers, statins, and/or aspirin, in accordance with each individual patient's risk factors and medical findings.²

Surgical treatment of AAAs can be performed by one of two general approaches: OSR or EVAR. Selection of the approach depends on the individual anatomy and on secondary factors such as patient age and estimated risks associated with anesthesia and surgery, with most patients undergoing EVAR.^{1,2}

TECHNIQUES AND OUTCOMES. For OSR of infrarenal AAAs, the abdominal aorta may be approached through either a transperitoneal or a left retroperitoneal exposure. A tube or bifurcated prosthetic graft is attached with suture directly to the proximal aorta, followed by sutured anastomosis to either the distal aorta (tube graft) or the common iliac arteries (bifurcation graft). Following restoration of lower extremity flow through the aortic graft, the aneurysm sac is sewn together to prevent contact between the prosthetic graft and the gastrointestinal tract. The operative mortality rate for OSR ranges from 1% to 4% in reports from single-institution centers of excellence, whereas mortality rates in state or national data bases range from 4% to 8%.² Operative complication rates range from 10% to 30%, with morbidity being related to cardiac, pulmonary, and renal complications and colonic ischemia. Because outcomes with OSR are related to hospital and surgeon volumes, there is a trend to recommend that OSR for AAAs be performed at centers with demonstrable operative mortality rates lower than 5%.

Late complications develop in as many as 15% to 30% of patients in long-term follow-up after OSR for AAAs. Such complications include problems related to the abdominal incision, para-anastomotic aneurysms (including false aneurysms secondary to disruption of the suture line and true aneurysms secondary to proximal aortic degeneration), graft infection, graft-enteric erosions or fistula, and graft limb occlusions with lower extremity ischemia. Late aneurysm formation at anastomotic sites after OSR is uncommon and has been reported in 1%, 5%, and 20% of patients, respectively, at 5, 10, and 20 years postoperatively.² Annual clinical follow-up with CT at 5-year intervals is generally recommended after open AAA repair.

ENDOVASCULAR ABDOMINAL AORTIC ANEURYSM REPAIR. In patients with suitable anatomy, EVAR offers a less invasive alternative to OSR. EVAR requires adequate nonaneurysmal proximal and distal attachment sites, and proximal attachment of the graft may be achieved via infrarenal or suprarenal fixation.² Several endografts have been approved by the Food and Drug Administration, each with its own unique design and method of fixation to the aortic wall.^{1,2} Randomized prospective trials comparing EVAR with OSR for asymptomatic infrarenal AAAs have demonstrated a lower 30-day mortality rate with EVAR than with OSR^{1,2} (Fig. 57-2), and a meta-analysis of these trials also reported a lower perioperative and intermediate survival benefit for the EVAR group.⁵ A significantly higher number of repeated interventions, however, occurred in the EVAR group.⁵

FIGURE 57-2 Comparison of EVAR and OSR in four major randomized trials of AAA repair. ACE = the Aneurysme de l'aorteabdominale, Chirurgie versus Endoprothese trial; DREAM = the Dutch Randomized Endovascular Aneurysm Management trial; EVAR-1 = the Endovascular Aneurysm Repair Trial 1; OVER, the Open Versus Endovascular Aneurysm Repair trial.

Large data bases have reported low mortality rates with EVAR, and when a high-risk cohort from the Veterans Affairs National Quality Improvement Program was analyzed, risk for mortality was found to be lower with elective EVAR than with OSR.² At long-term (~5-year) follow-up, however, AAA-related or all-cause mortality did not differ significantly between EVAR and OSR.⁶

Patients with ruptured AAAs may also benefit significantly from EVAR. In evaluating 27,750 patients discharged from the hospital after ruptured AAAs, EVAR was associated with lower overall in-hospital mortality than OSR was (32% to 41%, $P < 0.0001$).⁷ Data on 1037 patients treated by EVAR and 763 treated by OSR were collected from 13 centers. The overall 30-day mortality in all patients undergoing EVAR was 21%. In centers performing EVAR for all ruptured infrarenal AAAs, the 30-day mortality rate was 24%. When EVAR was compared with OSR from 1998 to 2009, EVAR was found to be associated with a lower 30-day mortality rate than OSR was, 16% versus 37%.⁸

With appropriate patient selection and accurate graft deployment, low perioperative mortality (1% to 2%) and complication (10% to 15%) rates can be achieved with EVAR for elective AAA repair.² These results have led to increased application of EVAR in patients with AAAs and appropriate anatomy. Currently, the options of EVAR and OSR, with their advantages and disadvantages, are considered in "medically fit" patients with suitable anatomy. Most patients select EVAR because of its early perioperative advantages and the "less invasive" nature of the procedure. At midterm follow-up after 2 and 4 years in the DREAM (Dutch Randomized Endovascular Aneurysm Repair) and EVAR-1 studies, EVAR was associated with a greater number of late complications and secondary reinterventions, and the initial reduction in mortality with EVAR was no longer present within 1 to 2 years.^{2,5,9} After a mean follow-up of 5 years, EVAR and OSR in the OVER (Open Versus Endovascular Repair) trial had similar survival rates, with EVAR demonstrating improved survival in those younger than 70 years, but not in older patients.⁶

The development of "endoleaks" (persistent blood flow in the aneurysm sac outside the endograft) is reported in almost 25% of patients at follow-up and is an important cause of aortic rupture after EVAR.² There are different types of endoleaks (Table 57-1). Type I endoleaks, which result from loss of complete sealing at the proximal (type IA) or distal (type IB) end of the stent-graft, lead to increased

TABLE 57-1 Classification of Endoleaks and Endotension

TYPE OF ENDOLEAK	SOURCE OF PERIGRAFT FLOW
I	Attachment site
A	Proximal end of stent-graft
B	Distal end of stent-graft
C	Iliac occluder
II	Branch leaks without attachment site leaks
A	Simple: one patent branch
B	Complex: two or more patent branches
III	Stent-graft defect
A	Junctional leak or modular disconnect
B	Fabric holes
IV	Stent-graft fabric porosity <30 days after placement
Endoleaks (time of detection)	Primary, present from the time of EVAR Secondary, appearing after previous negative CTA
Endotension	AAA enlargement with increased intrasac pressure after EVAR but without an endoleak visualized on CTA

From Moll FL, Powell JT, Fraedrich G, et al: Management of abdominal aortic aneurysms: Clinical practice guidelines of the European Society for Vascular Surgery. *Eur J Vasc Endovasc Surg* 41:S1, 2011.

pressure in the aneurysm sac and are associated with increased risk for rupture.¹ Even though some may seal spontaneously, this problem is ideally corrected during the EVAR procedure. Proximal endoleaks may be treated with extensions, stent placement, or endovascular obliteration of the space, whereas distal endoleaks are treated by extension techniques. Type II endoleaks, the most common, result from retrograde filling of the aneurysm sac by the lumbar or inferior mesenteric arteries. An initial conservative approach is often recommended for type II endoleaks; if sac enlargement is discovered, treatment is recommended. Type III endoleaks are caused by separation of components or disconnection of the endograft and require treatment. Type IV endoleaks are related to blood seeping through porous graft material and are self-limited. Persistence of type I and type II endoleaks may require conversion to open repair, but endovascular approaches may be successful.¹ Endotension, an enlarging AAA after EVAR without an endoleak and with a diameter increased to greater than 10 mm, usually requires repair. Late complications of EVAR (endograft migration, limb thrombosis), implant-related complications, and graft infection can also occur. Long-term radiographic surveillance is essential for monitoring the durability of the clinical results.

Imaging with contrast-enhanced CTA is typically performed at 1 month, 6 months, and annually after implantation of the device.¹ A reduced surveillance regimen may be appropriate in cases in which early success is achieved with the newer devices. Additionally, the use of color duplex ultrasonography to detect endoleaks and AAA enlargement may be appropriate for those with stable imaging findings. In conditions in which use of contrast material is prohibited (e.g., renal insufficiency, allergy), duplex ultrasound may be combined with non-contrast-enhanced CT for complete evaluation.

Widespread use of EVAR has demonstrated a reduction in early morbidity and mortality in patients with AAAs, especially in older adults. This advantage does not persist in long-term follow-up, however.⁶ It has been recommended that EVAR be performed at centers with very low in-hospital mortality (<3%) and a primary conversion rate to OSR of less than 2% for elective repair.² The

development of fenestrated and branched endografts is extending EVAR technology to increasingly challenging subsets of patients with aneurysms.

Thoracic Aortic Aneurysms

TAAAs have an estimated incidence of at least 5 to 10 per 100,000 person-years.¹⁰ The cause, natural history, and treatment vary depending on the location of the TAA. Aortic root or ascending aortic aneurysms are most common (≈60%), followed by aneurysms of the descending aorta (≈35%) and aortic arch (<10%).¹⁰ *Thoracoabdominal aortic aneurysm* refers to descending thoracic aneurysms that extend distally to involve the abdominal aorta.

Cause and Pathogenesis

Causes of TAAAs include genetically triggered, degenerative or atherosclerotic, mechanical, inflammatory, and infectious diseases (**Table e57-1**). Many of the genetic disorders preferentially involve the aortic root and ascending aorta. Smoking, hypertension, age, COPD, coronary disease, and a family history are all risk factors for TAAAs.¹¹ Cystic medial degeneration (CMD) describes degeneration and fragmentation of elastic fibers, loss of SMCs, increase in deposition of collagen, and replacement with interstitial “cysts” of mucoid-appearing basophilic-staining extracellular matrix (**Fig. e57-1**). CMD of the aorta is present in patients with MFS and many other genetically triggered TAA diseases. In addition, aging is associated with some degree of CMD, a process that may be accelerated by hypertension. These changes lead to progressive weakening of the aortic wall and eventually result in dilation and aneurysm formation.

Genetically Triggered Thoracic Aortic Aneurysm Diseases

Many disorders of the thoracic aorta have an underlying genetic trigger, some of which are associated with widespread syndromic features and others with thoracic aortic disease alone (**Table 57-2**). These disorders are associated with abnormalities in the aortic

TABLE 57-2 Genetically Triggered Conditions Associated with Aortic Dissection

Marfan syndrome (MFS)	Autosomal dominant disorder of connective tissue caused by <i>FBN1</i> mutation; incidence of 1 in ≈5000 individuals; multisystem manifestations, including ectopia lentis; mitral valve prolapse, aortic root aneurysm, aortic dissection; skeletal features (pectus deformities, scoliosis, arachnodactyly, hyperflexibility, tall stature, elongated fingers and toes); dural ectasia; spontaneous pneumothorax
Loeys-Dietz syndrome (LDS)	Autosomal dominant disorder caused by mutations in <i>TGFBR1</i> and <i>TGFBR2</i> , associated with aneurysms and dissections involving the aorta and branch vessels, often at relatively small diameters and young age; manifestations include craniofacial features (hypertelorism, craniosynostosis, cleft palate, bifid or broad uvula), bluish sclera, arterial tortuosity, velvety and hyperlucent skin, easily visible veins, clubfeet, skeletal abnormalities; phenotypes may vary, including those with more pronounced craniofacial features and those with more cutaneous features; ectopia lentis has not been described in LDS; mutations in <i>TGFBR2</i> lead to a syndrome with an overlap in clinical features of LDS and MFS
Familial thoracic aortic aneurysm (FTAA) syndromes	Autosomal dominant disorders with variable expression and penetrance leading to TAAAs and dissections at variable ages in families; <i>ACTA2</i> mutations occur in 10-15% of cases of FTAA and are associated with BAV disease, cerebral aneurysms, livedo reticularis, iris flocculi, PDA, moyamoya, and premature coronary artery disease; gene mutations causing familial TAAD include <i>ACTA2</i> , <i>TGFBR1</i> , <i>TGFBR2</i> , <i>FBN1</i> , <i>MYH11</i> , <i>MYLK</i> , <i>TGFBR2</i> , <i>SMAD3</i>
Vascular Ehlers-Danlos syndrome (vEDS)	Autosomal dominant disorder of collagen synthesis caused by a gene mutation in <i>COL3A1</i> leading to rupture and dissection of the aorta (usually the descending and abdominal aorta) and branch vessels; manifestations include flexible digits, hyperlucent skin with visible veins, varicose veins, typical facial appearance, and spontaneous rupture of the uterus or bowel
Bicuspid aortic valve (BAV)	Congenital condition affecting ≈1% of the population, familial in ≈9% of cases; often associated with dilation of the ascending aorta and carries increased risk for aortic dissection; gene mutations include <i>NOTCH1</i> and loci at 15q, 18q, 5q and 13q; may be associated with FTAA
Turner syndrome (TS)	Genetic disorder affecting 1 in 2000 live-born girls and caused by complete or partial loss of the second sex chromosome (XO, Xp); women with TS often have BAV and aortic coarctation; associated with ascending aortic dilation for body size and increased risk for aortic dissection, especially when associated with BAV, hypertension, and coarctation
Aneurysms-osteoarthritis syndrome	Autosomal dominant genetic disorder resulting from mutations in the <i>SMAD3</i> gene and associated with premature osteoarthritis, osteochondritis dissecans, skeletal features, aortic aneurysms, branch vessel aneurysms, and arterial tortuosity; overlap with LDS phenotype

TABLE e57-1 Disorders Associated with Thoracic Aortic Aneurysms

GENETICALLY TRIGGERED OR CONGENITAL	DEGENERATIVE	MECHANICAL	INFLAMMATORY AORTITIS	INFECTIOUS AORTITIS
Marfan syndrome	Atherosclerosis	Trauma	Takayasu arteritis	Syphilis
Loeys-Dietz syndrome	Hypertension	Aortic dissection	Giant cell arteritis	<i>Salmonella</i>
Vascular Ehlers-Danlos syndrome			Reiter syndrome	<i>Staphylococcus</i>
			Ankylosing spondylitis	
Familial thoracic aortic aneurysm syndromes			Psoriatic arthritis	<i>Streptococcus</i>
Bicuspid aortic valve			Juvenile RA	<i>Aspergillus</i>
Turner syndrome			Kawasaki disease	Mycobacteria
Congenital heart disease (tetralogy of Fallot, coarctation of the aorta, transposition, VSD, unicuspid aortic valve, supraaortic stenosis)			Behçet syndrome	HIV
			ANCA associated	
			Immune-mediated aortitis (IgG4 related)	
Osteogenesis imperfecta			Relapsing polychondritis	<i>Neisseria</i>
Noonan syndrome			Lupus erythematosus	<i>Candida</i>
Alport syndrome			Idiopathic aortitis	
			Sarcoidosis	
			Cogan syndrome	

ANCA = antineutrophil cytoplasmic antibody; HIV = human immunodeficiency virus; RA = rheumatoid arthritis; VSD = ventricular septal defect.

media, vascular SMCs, or contractile proteins, and many lead to overactivation of signaling pathways and downstream mediators.¹² Such disorders include MFS, LDS, vEDS, familial thoracic aortic aneurysm and dissection syndrome (FTAA/D), bicuspid aortic valve (BAV) disease, Turner syndrome (TS), and the aortopathy associated with many congenital heart diseases.

MFS, an autosomal dominant disorder of connective tissue, results from abnormal fibrillin-1 caused by mutations in the *FBNI* gene.¹³ In addition to directing elastogenesis and providing structural support to tissues, fibrillin-1 interacts with latent transforming growth factor-beta (TGF- β)-binding proteins and controls the activation and signaling of TGF- β . The abnormal fibrillin-1 in MFS leads to excess free TGF- β , which stimulates both canonic (SMAD) and noncanonic pathways. Data from a mouse model of MFS suggest that the noncanonic, TGF- β -dependent extracellular receptor kinase 1/2 (ERK1/2) cascade contributes critically to aortic disease.¹² Aortic dilation in MFS is most pronounced in the sinuses of Valsalva (**Fig. 57-3**, Videos 57-1 and 57-2). Angiotensin is important in TGF- β signaling and in blocking TGF- β , whether by neutralizing antibody or by the ARB losartan, which attenuated or prevented aortic aneurysm formation in genetically engineered MFS mice.¹² In a study of ARBs versus ACE inhibitors in mice with MFS, both reduced SMAD signaling in aortic tissue, but only ARB therapy reduced ERK activation; ARB therapy also more effectively reduced aortic growth. Inhibition of ERK activation (with the MEK1 inhibitor RDEA119) prevented abnormal aortic growth in MFS mice.¹² In children with MFS and very aggressive aortic disease, ARB therapy resulted in dramatic stabilization of aortic root size. Multiple trials comparing ARB therapy with beta blockers for MFS and examining their effects on aortic growth, circulating TGF- β levels, and pharmacogenetics are ongoing worldwide.^{12,14}

LDS, caused by mutations in *TGFBR1* and *TGFBR2*, is associated with craniofacial features (hypertelorism, bifid/broad uvula, cleft palate, craniosynostosis), arterial tortuosity, and aneurysms and dissections of the aorta and branch vessels.^{13,15} Patients with LDS may have notable cutaneous features, including easy bruisability, velvety hyperlucent skin with easily visible veins, and facial milia. Excess TGF- β signaling is suggested in the diseased tissues of patients with LDS.¹² Importantly, LDS has a much more aggressive vascular phenotype than MFS does, and performing prophylactic aortic surgery at smaller aortic root dimensions is recommended.^{13,15}

vEDS, which results from mutations in *COL3A1* causing abnormal collagen synthesis, may be associated with aortic aneurysms and dissection. Individuals with vEDS are at risk for spontaneous arterial dissection and rupture, often involving medium-sized arteries. Aortic root involvement is less common, with the descending and

abdominal aorta and aortic branch vessels being more frequently involved. Unlike MFS and LDS, the abnormal arteries in patients with vEDS are friable, thus making surgical repair difficult, complicated, and associated with increased risk.

TAA, in the absence of other genetic syndromes, may be familial. When TAA and dissection (TAAD) occurs in the absence of other syndromic features, it is often inherited as an autosomal dominant trait with decreased penetrance and variable expression—a disorder known as familial TAAD.¹⁴ An inherited pattern of TAA occurs in 20% of patients with TAAs.¹⁴ In familial TAAD, 66% of family members had TAAs, 25% had AAAs, and 8% had cerebral aneurysms. Several genes have been identified as being associated with TAAD, including *ACTA2*, *TGFBR1*, *TGFBR2*, *FBNI*, *MYH11*, *SMAD3*, *MYLK*, and *TGFBR2*. Mutations in *SMAD3* and *TGFBR2* may lead to syndromes exhibiting phenotypic overlap with LDS (**Table 57-2**). Although TGF- β signaling abnormalities underlie the pathogenesis in certain aneurysm syndromes, defects in SMC contractile function leading to aortic aneurysm and dissection are related to *ACTA2* and *MYH11* mutations.¹⁶ Fibrillin-1 microfibrils may participate in mechanotransduction in vascular SMCs, thereby linking fibrillin-1 in the matrix to intracellular actin filaments. Imaging of the aorta in family members often reveals asymptomatic aneurysms, and the incidence of aortic disease increases with advancing age. Some family members with TAAD have associated BAVs, cerebral aneurysm, and/or patent ductus arteriosus (PDA). *ACTA2* encodes smooth muscle alpha-actin, and mutation of this gene is the most common cause of familial TAAD; it affects approximately 14% and is associated with livedo reticularis, iris flocculi, premature coronary and cerebrovascular disease, PDA, and BAVs.¹⁴ The penetrance of aortic disease in familial TAAD caused by *ACTA2* mutations is approximately 50%.¹⁶ First-degree relatives of individuals with unexplained TAA or dissection should undergo aortic imaging or genetic testing by mutation analysis when a known mutation is present in the family.¹⁴

BAV disease affects approximately 1% of the population and may be associated with ascending aortic aneurysm, coarctation of the aorta, and aortic dissection.¹⁷ The aortopathy associated with BAV disease is one of the most common causes of ascending TAAs. Ascending aortic dilation does not result from “poststenotic dilation” but instead is related to underlying abnormalities of the aortic media. Hemodynamic effects may also play a role in the aortopathy. Turbulent flow and helical nesting flow have been described in the ascending aorta of patients with BAVs in the absence of significant valvular lesions and may contribute to aortic dilation.¹⁸ Ascending TAAs associated with BAVs may occur without associated aortic stenosis or regurgitation and may develop late after aortic valve replacement (AVR). Aortic aneurysms are more commonly associated with regurgitant BAVs than with stenotic BAVs, and late aneurysmal enlargement is more common after AVR performed for aortic stenosis than after AVR performed for aortic regurgitation in this population.^{19,20} When compared with patients with tricuspid aortic valves (TAVs), those with BAVs have larger aortic dimensions, even in childhood.¹⁸ The aortic enlargement in BAV disease often arises in the proximal to mid ascending aorta, thus making imaging of the entire extent of the ascending aorta important in patients with BAVs.¹⁴

CMD underlies the aortic aneurysm and risk for dissection associated with BAVs and can occur in the aortic wall of patients with BAVs, even without significant aneurysm formation.¹⁸ When compared with TAV aneurysms, BAV aneurysms exhibit a distinct pattern of CMD, increased apoptosis, increased MMP-2 activity, and greater expression of death-promoting mediators by infiltrating lymphocytes.¹⁸

BAVs and ascending aortic aneurysm may be familial and associated with risk for aortic dissection and may be inherited as an autosomal dominant disorder with variable expressivity and incomplete penetrance.¹⁸ Altered TGF- β signaling has been recognized in BAV aneurysm disease.¹⁸ Potential loci at 15q, 18q, 5q, and 13q have been suggested for BAVs and aortic aneurysms.¹⁸ *NOTCH1* mutations have been found in a small number of families with BAVs and TAAs. First-degree relatives of a patient with BAV disease may have aortic dilation and/or abnormal aortic elastic properties, even in the absence of BAV

disease.¹⁸ All family members should undergo evaluation for BAVs and ascending aortic aneurysm.¹⁴

TS, which affects 1 in 2000 live-born girls, results from complete or partial loss of a second sex chromosome (XO, Xp). Approximately 50% of patients with TS have cardiovascular defects, including BAVs in approximately 20% and coarctation of the aorta in approximately 12%. Aortic dilation occurs in TS and is associated with CMD. Abnormal TGF- β signaling may also contribute to the aortic disease in TS. Patients with TS have an estimated 100-fold greater risk for aortic dissection than do age-matched controls.²¹ Most women with TS who suffer aortic dissection have risk factors, including BAVs, coarctation of the aorta, or systemic hypertension (Fig. e57-2).¹⁴ In women with TS but without risk factors for aortic dissection, reevaluation of the aorta is recommended every 5 to 10 years or when clinically indicated (such as when contemplating pregnancy).¹⁴ Because patients with TS have short stature, ascending aortic dimensions should be evaluated in relation to body surface area. TS patients have increased aortic diameter relative to body surface area and a higher risk for dissection at smaller absolute aortic diameters.

CMD has been identified in several types of congenital heart disease other than BAVs, including coarctation of the aorta, transposition of the great vessels, ventricular septal defect, and tetralogy of Fallot (TOF). In TOF, aortic dilation is associated with male sex, with a longer interval from palliation to definitive repair, and with pulmonary atresia and a right-sided aortic arch and may lead to aortic regurgitation, aortic aneurysm, and rarely, aortic dissection.²²

Atherosclerosis

Atherosclerotic aneurysms are less common in the ascending aorta and, when present, are associated with diffuse aortic atherosclerosis. Isolated arch aneurysms may be caused by atherosclerosis, penetrating aortic ulcers, CMD, and rarely, syphilis or other infections. The major cause of descending aortic aneurysms is atherosclerosis, but genetic disorders may be causative. These aneurysms tend to originate just distal to the origin of the left subclavian artery, may be either fusiform or saccular, and may extend into the abdominal aorta or coexist with AAAs.

Syphilis and Aortitis

Cardiovascular syphilis occurs in the tertiary stage and typically involves the ascending aorta and arch. Aortitis rarely occurs today because of antibiotic treatment of syphilis early in its course. Cardiovascular syphilis becomes evident after a latent period of at least 10 to 25 years. Because of the inflammatory response, destructive changes occur in the muscular and elastic tissue, along with fibrous and calcific degeneration. Pathologic features include lymphocytic and plasma cell inflammation in the adventitia, with the classic appearance of a “tree bark” or wrinkled appearance of the aortic intima. Ascending aortic aneurysm formation occurs in 40% of cases. Tertiary syphilis may cause aortic valvulitis, aortic regurgitation, and coronary ostial stenosis.

Infectious aortitis is discussed later in this chapter (see **Bacterial Infections of the Aorta**). Other causes of TAAs include noninfectious aortitis such as giant cell arteritis, other vasculitides, and idiopathic aortitis. Noninfectious aortitis may underlie aortic aneurysms in 2% to 8% of TAAs and is discussed in other chapters. Aortic trauma is discussed in **Chapter 72**.

Clinical Manifestations

Most patients with a TAA are asymptomatic, and the aneurysm is discovered incidentally on chest radiography, echocardiography, CT, or MRI. Findings on physical examination such as aortic regurgitation may lead to further imaging and diagnosis of TAA. Symptoms of TAAs are usually related to a local mass effect, progressive aortic regurgitation, heart failure from aortic root dilation, or systemic embolization as a result of mural thrombus or atheroembolism. Obstruction of the superior vena cava or innominate vein may be due to ascending aorta or arch aneurysms. TAAs may compress the trachea, bronchus, or esophagus and lead to symptoms. Persistent chest or back pain may occur because of a direct mass effect from the TAA, with compression of intrathoracic structures or erosion into adjacent bones.

The most serious complications of TAAs are rupture and dissection (Fig. 57-4, Fig. e57-3). Aortic rupture leads to sudden severe chest or back pain. Rupture into the pleural cavity (usually left) or into the mediastinum is associated with hypotension, rupture into the esophagus leads to hematemesis from an aorto-esophageal fistula, and rupture into the bronchus or trachea results in hemoptysis. Infected TAAs are more commonly associated with fistulas. Acute aortic expansion, contained rupture, and pseudoaneurysm can cause severe chest or back pain. Thoracic aortic dissection (discussed later) is more common than rupture.

Diagnosis

Many TAAs are evident on chest radiographs (Fig. 57-5), with features including a widened mediastinum, prominent aortic knob, or displaced trachea. Smaller aneurysms, especially saccular ones, may not be visible on chest radiographs. Aneurysms involving the sinuses of Valsalva and aortic root are often “hidden” behind the sternum, mediastinal structures, and vertebrae and may not be visualized on chest radiographs. Aortic tortuosity and unfolding in older adults may also mimic or mask TAAs. Thus chest radiographs cannot exclude the diagnosis of TAA.

FIGURE e57-2 Contrast-enhanced CT scan of a 47-year-old woman with TS demonstrating an elongated aortic arch, coarctation of the aorta (*white arrow*), dilated proximal descending aorta, and acute type B aortic dissection (*black arrow*).

FIGURE e57-3 Non-contrast-enhanced CT demonstrating rupture and hemorrhage (*arrows*) from a descending thoracoabdominal aortic aneurysm (Ao).

Transthoracic echocardiography (TTE) is an excellent modality for imaging the aortic root (**Fig. e57-4** and Video 57-3; also see **Fig. 57-3** and Video 57-1) and can be used to visualize TAAs involving the sinuses of Valsalva and often the proximal ascending aorta, aortic arch, and proximal descending aorta. Aortic root size is dependent on age, height or body surface area, and sex, and nomograms can be used to predict normal ranges.^{14,23} Although TTE does not thoroughly characterize aortic arch and descending TAAs, transesophageal echocardiography (TEE) can image most of the thoracic aorta and has become widely used for detection of aortic dissection.

Contrast-enhanced CT and MRA are preferred over aortography in most cases of TAA to define both aortic and branch vessel anatomy. In the setting of a tortuous aorta, axial images alone can be misleading and may “overstate” the true dimension of the aorta. When the axial images cut through the descending aorta at a plane that is off-axis, it results in a falsely large aortic diameter. Multidetector CTA allows reconstruction of the axial data into three-dimensional images, and the aorta may be measured in a true cross section to obtain an accurate diameter (**Fig. 57-6**). CTA and contrast-enhanced MRI are highly accurate in the evaluation and follow-up of patients undergoing endovascular TAA therapy. Importantly, the echocardiogram generally measures the internal diameter, whereas CT and/or MRI measure the external diameter of the aorta, which is expected to be 0.2 to 0.4 cm larger than the internal diameter.¹⁴

Natural History

Many factors influence the natural history of TAAs. Genetically triggered TAAs behave differently from atherosclerotic aneurysms. The location and size of the TAA also affect its rate of growth and likelihood of rupture or dissection. Surgery is recommended when the TAA reaches a certain size threshold in appropriate candidates. Endovascular therapy is changing the approach to management in operative candidates who were previously considered high risk.

TAAs are relatively indolent, with a growth rate of 0.1 to 0.2 cm/year and marked individual variability.^{10,24} Larger aneurysms grow

faster than smaller ones. Aneurysms of the descending aorta have a much greater growth rate (0.19 cm/year) than do those of the ascending aorta (0.07 cm/year), and dissected TAAs grow more rapidly (0.14 cm/year) than those without dissection (0.09 cm/year).¹⁰ Patients with MFS have a more rapid aneurysm growth rate than do those without MFS. The mean rate of rupture or dissection was 2% per year for aneurysms smaller than 5 cm in diameter, 3% per year for those 5.0 cm to 5.9 cm, and 7% per year for those 6.0 cm or larger. The relative risk for dissection or rupture of an aneurysm in a patient with MFS was found to be 3.7, and for female patients with MFS it was 2.9.

Risk factors for increased growth and rupture of TAAs include older age, female sex, COPD, hypertension, cigarette smoking, rapid aneurysm growth, pain, aortic dissection, and a positive family history.^{10,14} Aortic diameter is the most important risk factor for aneurysm rupture, dissection, and death. In a study conducted at the Yale Center for Aortic Disease, the median aortic diameter at the time of dissection or rupture of the ascending aorta or aortic arch was 6 cm. For ascending aortic aneurysms larger than 6 cm, the risk for rupture, dissection, or death was 15.6%.²⁴ Sex and body surface area may also play an important role in predicting complications of aneurysms.^{14,24} Some have proposed using aortic cross-sectional area and body height,¹⁴ and the Aortic Risk Calculator (<http://www.aorta.yale.edu>) uses height, weight, and aortic size to calculate a yearly risk for rupture or dissection.²⁵ Patients with an aortic size index (ASI) of less than 2.75 cm/m² had a complication rate of 4%, those with an ASI between 2.75 and 4.25 cm/m² had an event rate of approximately 8%, and those with an ASI higher than 4.25 cm/m² had an event rate of 20% to 25%.²⁴

BAV ascending aortic aneurysms have a higher growth rate (0.19 cm/year) than do aneurysms in patients with a TAV (0.13 cm/year).¹⁸ In the International Registry of Acute Aortic Dissection (IRAD), when the ascending aortic dissection was associated with a BAV, the average size of the aorta at the time of dissection was 5.4 ± 1.8 cm.¹⁸ The ascending aorta averaged 5.2 cm at the time of dissection in a series of patients with BAV-associated aortic dissection from Yale.¹⁸

In general, surgical replacement of the aorta should be performed when the ascending aortic diameter reaches 5.5 cm and, in the setting of BAV aneurysm, MFS, and familial TAA syndromes, when it reaches 5 cm.^{14,25} In adults with LDS, surgery is recommended when the aortic root measures 4.2 cm by TEE or 4.4 to 4.6 cm by CT or MRI,¹⁴ although some experts recommend surgery in patients with LDS once the aortic root is larger than 4 cm.^{13,15} In TS, prophylactic surgery should be considered when the ascending aorta is 3.5 cm or larger or 2.5 cm/m² or larger.²¹ Surgical timing also depends on the family history, sex, rate of aneurysm growth, body size, coexisting aortic valve disease, need for other heart surgery, comorbid conditions, and patient and physician preference.

Rupture and acute dissection are the major complications of TAAs (see **Figs. 57-4** and **e57-3**). Less than half of patients with rupture arrive at the hospital alive; mortality at 24 hours reaches 75%. Acute dissection is discussed later in this chapter.

Management

Surgical Treatment

ASCENDING THORACIC AORTIC ANEURYSMS. Treatment of ascending TAAs involves resection and grafting of the ascending aorta with or without concomitant AVR. Cardiopulmonary bypass is necessary for the removal of ascending aortic aneurysms, and partial bypass to support the circulation distal to the aneurysm while the aortic site being repaired is crossclamped is often advisable when resecting descending TAAs. TAAs are generally resected and replaced with a prosthetic graft. A composite graft consisting of a Dacron tube with a prosthetic aortic valve sewn into one end (composite aortic repair, or the modified Bentall procedure) is generally the method of choice in treating ascending TAAs involving the root and associated with significant aortic valve disease. The valve and graft are sewn directly into the aortic annulus, and the coronary arteries are reimplanted into the Dacron graft. For elective aneurysm resection, the

FIGURE 57-7 Valve-sparing aortic root procedures. **A**, Skeletonized aortic valve, coronary buttons. **B**, Reimplantation technique (David procedure). The surgeon fixes the graft to the left ventricular outflow tract at the subannular level and reimplants the valve and commissures inside the fabric graft, thus fixing the size of the aortic annulus permanently. **C**, Remodeling technique (Yacoub procedure). The surgeon sews the graft to the remaining aortic wall tissue around the commissures after the insertion line of the aortic cusps, thus leaving the annulus mobile (but unsupported)—which allows billowing of the graft, called “neosinuses.” (From Kruger T, Conzelmann LO, Bonser RS, et al: *Acute aortic dissection type A*. *Br J Surg* 99:1331, 2012.)

risk for death or stroke ranges from 1% to 5% depending on the disease, patient population, and surgical experience.^{14,26} The risk for morbidity and mortality increases with the need for arch dissection. Emergency operations on the proximal aorta carry much higher risk, averaging approximately 22%.²⁶ Patients with structurally normal aortic valve leaflets and those whose aortic regurgitation is secondary to dilation of the sinotubular junction or aortic annulus may be able to undergo a valve-sparing root replacement—reimplanting the native valve within a Dacron graft (David procedure) or by remodeling the aortic root (Yacoub procedure) (Fig. 57-7). The reimplantation technique is preferable to the remodeling technique because the annulus is stabilized, thereby preventing aortic dilation and late aortic regurgitation.²⁷

A pulmonary autograft (the Ross procedure) is an alternative to a composite aortic graft in appropriate candidates. This procedure involves replacing the native aortic valve and root with the patient's own pulmonary root, which is transplanted into the aortic position. The pulmonary root is replaced with a cryopreserved homograft root. The Ross procedure carries risks of late autograft aneurysm formation and should not be used in patients with genetically triggered aortic root diseases; its use is controversial in the setting of BAV and aortic disease.¹⁸ Another alternative is the use of cryopreserved aortic allografts (cadaveric aortic root and proximal ascending aorta), but durability issues and late aortic calcification limit this choice. The risk for mortality with thoracic aortic surgery is reported as follows for elective repair: composite valve graft, 1% to 5%; separate AVR and ascending aortic repair, 1% to 5%; valve-sparing root replacement, less than 1% to 1.5%; and BAV and ascending aortic repair, 1.5%.¹⁴

AORTIC ARCH ANEURYSMS. Aortic arch aneurysms are more difficult to treat surgically because reconstruction of the aortic arch vessels requires interruption of blood flow to these vessels.¹⁴ In some cases a proximal hemiarch resection is performed—the arch vessels are left intact, with the descending aorta as a roof, and the remaining arch is replaced. Extended arch resection can be performed either by removing the entire arch tissue and using branched grafts to replace the arch and great vessels, by using bypasses constructed to each great vessel, or by reimplanting an island of arch tissue that includes the origins of the great vessel.¹⁴ Several methods can be used for cerebral protection during arch surgery. Deep hypothermic circulatory arrest has been a traditional method. If the aneurysm extends partially into the descending thoracic aorta, the polyester graft is extended as an elephant trunk into the descending portion of the aneurysm, and a secondary procedure is needed to complete the repair.^{14,28,29} In this procedure the distal anastomosis is created to the midportion of a graft. The distal edge of this graft is within the lumen of the distal aorta and thus can be retrieved without manipulation of the arch.²⁹ The procedure has recently been modified by using a covered endovascular stent-graft attached to a vascular graft to allow fixation of the stent-graft within the descending aorta and vascular graft reconstruction of the aortic arch.³⁰ This “frozen elephant trunk” procedure allows total replacement of the arch and descending aortic in a single stage for complex aneurysms and has also been extended to the treatment of acute type A dissection.²⁸ Spinal cord injury has been reported, however, in 9% of frozen elephant trunk procedures performed for extensive chronic aortic dissection.²⁸ Treatment of arch aneurysms is associated with higher morbidity and mortality rates than ascending aneurysms are, with a 2% to 7% risk for both death and stroke.^{14,29} Endovascular techniques and extra-anatomic reconstructions are being used to treat complex aortic arch aneurysms and to complete elephant trunk procedures.^{14,28}

DESCENDING THORACIC ANEURYSMS. Treatment of descending TAAs involves resection and grafting of the aneurysmal segment with a polyester graft. The procedures are performed with partial femorofemoral bypass or atriorectal bypass to maintain retrograde perfusion to critical arterial branches; they are associated with a perioperative mortality of 10% or less and a paraplegia rate of approximately 2%, depending on the extent of repair.¹⁴ Five-year survival rates after descending TAA resection approach 70%. Endovascular devices approved for the treatment of patients with TAAs and appropriate anatomy are discussed later.

THORACOABDOMINAL ANEURYSMS. Thoracoabdominal aneurysms can extend from the subclavian artery to the iliac vessels (see Fig. 57-6). The Crawford classification describes the extent of aneurysm repair, and this predicts morbidity, mortality, and risk for paralysis. Crawford type I repair extends from the proximal descending aorta above the T6 vertebra to below the renal arteries; type II is the highest risk group, with the repair extending from the proximal descending aorta above T6 to below the renal arteries; type III repair extends from the distal descending aorta below T6 to below the diaphragm; and type IV repair extends from the diaphragm and involves most of the abdominal aorta.¹⁴ Resection of these aneurysms is complex and usually performed through an extensive thoracoabdominal incision. The procedure requires bypass to maintain perfusion of the lower extremities and the mesenteric vessels. Spinal fluid drainage and other techniques are performed, as for thoracic aneurysms, to diminish the risk for paraplegia and paraparesis.¹⁴ The mortality rate in low-risk patients is 3% to 10%, with a paraplegia rate of 3% to 5%, depending on the extent of the repair.¹⁴ Emergency surgery for rupture or leak carries a mortality rate of 80%.¹⁴

ENDOVASCULAR REPAIR OF THORACIC ANEURYSMS. Thoracic endovascular aneurysm repair (TEVAR) is a far less invasive alternative to OSR of descending TAAs, with lower morbidity and mortality rates—but the aortic anatomy must have adequate proximal and distal landing zones of at least 20 to 25 mm in length and diameters that accommodate the endograft, as well as adequate vascular access.^{14,31} Approved devices in the United States include the Gore TAG Thoracic Endoprosthesis (W.L. Gore and Associates, Inc., Flagstaff, Ariz), the Talent Thoracic Stent Graft System Endovascular

FIGURE 57-8 Thoracic endovascular graft prosthesis. Examples shown are of a Conformable Gore TAG Thoracic Endoprosthesis. (Courtesy W.L. Gore & Associates, Inc., Flagstaff, Ariz.)

Graft (Medtronic Vascular, Santa Rosa, Calif), and the Zenith TX2 TAA Thoracic Endovascular Graft (Cook, Inc., Bloomington, Ind) (Fig. 57-8).³¹

The results of prospective trials comparing TEVAR with OSR in low-risk patients demonstrate that endovascular repair of anatomically suitable TAAs and large penetrating ulcers has a significantly lower perioperative morbidity and mortality rate than OSR does. The results of the three stent-graft trials in the TEVAR arms reported rates of 1.9% to 2.1% for mortality, 2.4% to 4% for stroke, 4.4% to 7.2% for paraparesis, and 1.3% to 3% for paralysis.³² In the OSR groups in the three multicenter trials, mortality and neurologic morbidity rates ranged from 5.7% to 11.7% for mortality, 4.3% to 8.6% for permanent stroke, 5.7% for paraparesis, and 3.4% to 8.5% for paralysis.³² Others have reported that the data do not conclusively demonstrate that the risk for spinal cord injury is less with TEVAR than with OSR.¹⁴

The anatomic configuration of the ascending aorta and transverse arch makes applying these techniques and devices challenging in these proximal segments. Hybrid techniques using extra-anatomic bypass procedures can gain or create an appropriate proximal landing and seal zone for the endovascular graft in the aorta without the need for major open thoracic surgery. In up to 50% of TEVAR procedures the stent-graft intentionally covers the left subclavian artery.¹⁴ Transposition of the left subclavian artery or a left carotid-to-subclavian bypass can be performed to allow attachment and seal of an endovascular graft across the takeoff of the subclavian artery. Subclavian artery occlusion without reconstruction is associated with an increased risk for cerebrovascular complications, including stroke, which can be avoided by reconstruction before endovascular exclusion of the subclavian artery.³¹ If all the branches of the aortic arch need to be excluded for appropriate endovascular repair of an arch aneurysm, other options are available. Complete extra-anatomic aortic arch debranching can be performed, with reconstruction of the arch branches and subsequent carotid and subclavian bypasses as necessary. Another option is to perform an elephant trunk procedure under cardiopulmonary arrest; a prosthetic graft is sutured to the healthy portion of the ascending aorta and aortic arch, and branches of the aortic arch are left intact. This creates a proximal attachment zone of a predetermined length and diameter that can be extended distally with an endovascular graft to complete the aneurysm repair. Bypasses to all the aortic arch branches can also be performed from the proximal ascending aortic arch in selected patients, with a healthy portion left in the ascending aorta for attachment and seal of an endovascular graft. This procedure does not require aortic crossclamping or cardiopulmonary arrest and is probably associated with lower perioperative morbidity. Precurved and branch devices are being developed to manage patients with complex

thoracic and thoracoabdominal aneurysms. Debranching procedures involving visceral vessels may be necessary before proceeding with endograft implantation.¹⁴

Open and endovascular repair of thoracic aneurysms is associated with a variety of significant risks, including cardiac, pulmonary, renal, and cerebrovascular complications. Spinal cord dysfunction with the development of paraparesis or paraplegia is a major source of morbidity. Drainage of cerebrospinal fluid from the spinal cord has been used in combination with a mean arterial pressure of at least 70 mm Hg to diminish the rate of spinal cord complications.¹⁴

Rupture of a descending TAA is often fatal before hospital admission. In a meta-analysis, endovascular repair of ruptured descending TAAs was associated with a significantly lower in-hospital mortality rate (19%) than OSR was (33%), but complications develop after TEVAR in many patients.³³ Endovascular grafts have an additional unique group of complications that can occur, and up to 10% of device-related complications take place in the first 30 days after the procedure.¹⁴ Material fatigue and migration of the endovascular graft are rare with the currently available endovascular thoracic devices. Endoleaks are the most common complication of endovascular repairs and occur in 10% to 20% of patients.¹⁴ Type I endoleaks are associated with reperfusion and pressurization of the aneurysm sac from the proximal or distal end of the graft. Type III endoleaks result from separation of the endograft components. Type I and III endoleaks require treatment to avoid continued aneurysm growth and potential rupture. Type II endoleaks are rare and associated with persistent flow from intercostal branches; they rarely necessitate reintervention because most seal during long-term observation. Patients require serial imaging surveillance after TEVAR. Over a 5-year follow-up period, the mean aortic diameter after TEVAR decreased from 61 to 55 mm.³² The rate of freedom from reintervention on the aortic segment treated was 85% at 10 years.

Medical Management

Treating hypertension and smoking cessation are important tenets of management because they are risk factors for TAAs.³⁴ Home blood pressure monitoring may help confirm adequate control. In patients with atherosclerotic TAAs, cholesterol lowering is also recommended. Beta blockers are recommended for patients with MFS.¹⁴ Even though no randomized trials currently exist to support it, beta blockers are often recommended in non-MFS patients with TAAs and in patients after aneurysm repair. Based on animal model data, when antihypertensive medications are needed, ARBs or ACE inhibitors are recommended.¹⁴ Because TGF- β signaling is related to the pathogenesis of MFS (and LDS), drugs affecting this signaling pathway, such as ARBs, may provide benefit.^{12,14} Animal models of the MMP inhibitor doxycycline also demonstrate benefit in MFS, but no data are available in humans with TAAs. Statins, by suppressing the inflammatory pathways involving the reduced form of nicotinamide adenine dinucleotide/nicotinamide adenine dinucleotide phosphate (NADH/NADPH) oxidase system independent of lipid lowering or by influencing the activity of MMPs and plasminogen activators and their inhibitors, may benefit patients with TAAs.³⁵ In animal models of MFS, pravastatin prevented TAAs, but no prospective data show that statins prevent TAAs in humans.³⁴

Long-term surveillance of the aorta with imaging is imperative (Table 57-3). After discovery of an aneurysm, patients should be reevaluated in 6 months to document stability of the aneurysm. In general, for degenerative TAAs, annual imaging should be performed when the aorta is between 3.5 and 4.4 cm, and biannual imaging should be performed for aneurysms between 4.5 and 5.4 cm. For relatively small aneurysms that imaging shows to be stable from year to year, imaging may be performed every 2 to 3 years.¹⁴ In patients with MFS, BAV, and familial TAAD, annual imaging is recommended for aortic sizes of 3.5 to 4.4 cm and biannual imaging for aortic sizes of 4.5 to 5 cm. In LDS, imaging from the head to the pelvis is recommended because of the potential for widespread aneurysms.¹⁴

Lifestyle modification is necessary for patients with TAAs, including awareness of the condition and the risk for aortic dissection and rupture. Avoidance of strenuous physical activity, especially

TABLE 57-3 Suggested Imaging Surveillance of Asymptomatic Thoracic Aortic Aneurysms*

Initial discovery of aneurysm	Repeated imaging at 6 months to document stability
Degenerative aneurysm [†]	
3.5-4.4 cm	Annual imaging
4.5-5.4 cm	Annual to biannual imaging
MFS, BAV with TAA, and familial TAA	
3.5-4.4 cm	Annual imaging
4.5-5.0 cm	Biannual imaging
LDS [‡]	
<4 cm	At least annual imaging
>4 cm	Biannual imaging

*For aneurysms growing rapidly, more frequent imaging is recommended. Management of TAA must take into account the family history, age, body size, sex, rate of aneurysm growth, and underlying disease.

[†]For relatively small degenerative aneurysms found by imaging to be stable from year to year, imaging may be performed every 2 to 3 years.¹⁴

[‡]Some recommend surgery for aortic root dimensions larger than 4 cm in adults with LDS, whereas the American College of Cardiology/American Heart Association guidelines for thoracic aortic disease recommend prophylactic surgery at 4.2 cm by TEE and 4.4 to 4.6 cm by CT or MRI.¹⁴

isometric exercise and weightlifting, is important³⁴; this may have an impact on work-related recommendations. Pregnancy is associated with an increased risk for aortic dissection in those with MFS and related disorders, and management strategies must encompass this risk.^{7,34,36} Because many diseases that lead to TAAs are familial, aortic imaging is recommended for first-degree relatives of patients with TAAs and/or dissection to identify those with asymptomatic disease. If a patient has a mutant gene (*FBNI*, *TGFBR1*, *TGFBR2*, *COL3A1*, *ACTA2*, *MYH11*, *SMAD3*, *TGFBR2*, among others), first-degree relatives should undergo counseling and mutation testing.¹⁴ Then only relatives with the genetic mutation should undergo aortic imaging. If no mutation is identified, evaluation and imaging are recommended for first-degree relatives. If a first-degree relative is found to have thoracic aortic disease, further screening of second-degree relatives is reasonable.¹⁴

AORTIC DISSECTION

Acute aortic syndromes include classic aortic dissection, aortic intramural hematoma (IMH), and penetrating atherosclerotic ulcer (PAU) (Fig. 57-9). In approximately 90% of acute aortic syndromes, classic aortic dissection is present, with intimal disruption leading to a dissection plane in the aortic wall that may propagate anterogradely (or less commonly, retrogradely) throughout the length of the aorta. In classic aortic dissection, an intimal flap exists between the two lumina (true and false lumina). In 5% to 10% of acute dissection cases in Western series, bleeding in the aortic wall occurs without evidence of an intimal tear or dissection flap. This variant of aortic dissection is known as an aortic IMH. PAUs also lead to acute aortic syndromes.

Ascertaining the exact incidence of aortic dissection is difficult because many patients die before the condition is recognized. Population studies in the United States have estimated the incidence of aortic dissection to range from 2 to 3.5 cases per 100,000 person-years.¹⁴ Aortic dissection occurs at least twice as often in males as in females. In Sweden, the incidence of dissection in men is reported to be 16 per 100,000 yearly¹⁴; in necropsy series the prevalence of aortic dissection ranges from 0.2% to 0.8%.³⁷ The early mortality rate in patients with acute aortic dissection is very high, with up to a 1% per hour death rate reported in the first several hours before surgery for type A dissection.^{14,38} Ascending aortic dissection occurs most

FIGURE 57-9 Acute aortic syndromes. **A**, Classic aortic dissection. **B**, Aortic intramural hematoma. **C**, Penetrating atherosclerotic ulcer.

commonly in individuals between 50 and 60 years of age, and descending aortic dissection more commonly occurs in older individuals, with a peak at 60 to 70 years of age. Because dissection is uncommon, a high index of suspicion for acute aortic dissection must be maintained when evaluating patients with unexplained chest or back pain or a syndrome complex compatible with this diagnosis. Immediate recognition of dissection and timely institution of medical and/or surgical therapy are necessary for improved survival.

There are two main hypotheses for acute aortic dissection (Fig. e57-5): (1) a primary tear in the aortic intima with blood from the aortic lumen penetrating into the diseased media and leading to dissection and creation of the true and false lumina and (2) primary rupture of the vasa vasorum leading to hemorrhage in the aortic wall, with subsequent intimal disruption creating the intimal tear and aortic dissection. The pressure of the pulsatile blood within the aortic wall after dissection leads to extension of the dissection. Aortic dissections usually propagate in an antegrade direction because of the pressure wave from the aortic blood, but they occasionally extend in a retrograde direction. The dissection flap may be localized or may spiral the entire length of the aorta. Arterial pressure and shear forces may lead to further tears in the intimal flap and produce exit sites or additional entry sites for flow of blood into the false lumen (Fig. 57-10). Distention of the false lumen with blood causes the intimal flap to compress the true lumen and narrow its caliber and thus may lead to malperfusion syndromes.

Classification

The two major classification schemes for aortic dissection—the DeBakey classification and the Stanford classification—are based on the location of the dissection (Fig. 57-11; Table 57-4). The ascending aorta is proximal to the brachiocephalic artery, and the descending aorta begins distal to the left subclavian artery. The DeBakey classification divides dissections into types I, II, and III. DeBakey type I dissections originate in the ascending aorta and extend at least to the aortic arch and often to the descending aorta—frequently all the way to the iliac arteries (Fig. 57-12). Type II dissections involve the ascending aorta alone. Type III dissections begin in the descending aorta, usually just distal to the left subclavian artery, and may be classified further according to whether the dissection stops above the diaphragm [IIIa] or extends below the diaphragm [IIIb]. The Stanford

FIGURE e57-5 Hypotheses of acute aortic dissection. **A**, A primary tear in the intima leads to blood entering the media (*arrow*) and to the development of a cleavage plane (dissection) that creates the true and false lumina. **B**, Primary rupture of the vasa vasorum results in hemorrhage in the aortic wall, which then precipitates disruption of the intima (*arrow*) and leads to an intimal tear and aortic dissection.

FIGURE 57-10 Contrast-enhanced CT scan of an aortic dissection demonstrating a fenestration in the intimal flap (arrow) with contrast material flowing from the small, densely opacified true lumen into the less opacified and larger false lumen of the aorta.

FIGURE 57-11 Classification schemes of acute aortic dissection.

classification categorizes dissections into type A and type B based on whether the ascending aorta is involved. Stanford type A dissections involve the ascending aorta (with or without extension into the descending aorta), and Stanford type B dissections do not involve the ascending aorta. Thus dissections that involve the aortic arch but not the ascending aorta are characterized as type B in the Stanford classification. Others classify dissections as “ascending” or “descending.”

Most ascending aortic dissections begin within a few centimeters of the aortic valve, and most descending aortic dissections begin just distal to the left subclavian artery. Approximately 65% of intimal tears occur in the ascending aorta, 30% in the descending aorta, less than 10% in the aortic arch, and approximately 1% in the abdominal aorta. Treatment depends on the site, with emergency surgery being recommended for acute type A dissections and initial medical therapy recommended for type B dissections. Aortic dissection is also classified according to its duration, being “acute” when present for less than 2 weeks and “chronic” when present for more than 2 weeks.

TABLE 57-4 Classification Schemes of Acute Aortic Dissection

DeBakey Classification	
Type I	Originates in the ascending aorta and extends at least to the aortic arch and often to the descending aorta (and beyond)
Type II	Originates in the ascending aorta and confined to this segment
Type III	Originates in the descending aorta, usually just distal to the left subclavian artery, and extends distally
Stanford Classification	
Type A	Dissections involving the ascending aorta (with or without extension into the descending aorta)
Type B	Dissections not involving the ascending aorta

FIGURE 57-12 Contrast-enhanced CT scan demonstrating acute type A aortic dissection with enlargement of the ascending aorta and intimal flaps (arrows) in the ascending and descending aorta. Both the true lumen (TL) and the false lumen are opacified with contrast material in this example.

Some classify dissections between 2 and 6 weeks after onset as “sub-acute” and those more than 6 weeks after the onset of pain as “chronic.”¹⁴ The morbidity and mortality rates associated with acute dissection are highest in the first 2 weeks, especially within the first 24 to 48 hours.¹⁴

Cause and Pathogenesis

Several conditions predispose the aorta to dissection (Table 57-5), most resulting from disruption of the normal architecture and integrity of the aortic wall or marked increases in aortic wall shear stress (see earlier discussion in the section on TAAs). Hypertension occurs in approximately 75% of all patients who suffer aortic dissection. Hypertension leads to changes in arterial wall structure, including intimal thickening, calcification, and adventitial fibrosis. These alterations may affect the elastic properties of the arterial wall and increase stiffness and thereby predispose to aneurysm or dissection. However, hypertension alone is not usually associated with significant aortic root dilation, and the vast majority of hypertensive patients never suffer aortic dissection. Hypertension occurred in 72% of the 464 patients in the IRAD, with atherosclerosis in 31%, AVR in 5%, coronary artery bypass grafting (CABG) in 4%, and iatrogenic dissection in 4%.³⁹

TABLE 57-5 Risk Factors for Aortic Dissection

Hypertension
Genetically triggered thoracic aortic disease
Marfan syndrome (MFS) (<i>FBNI</i>)
Bicuspid aortic valve (BAV)
Loeys-Dietz syndrome (LDS) (<i>TGFBR1</i> , <i>TGFBR2</i>)
Familial thoracic aortic aneurysm (FTAA) (<i>ACTA2</i> , <i>TGFBR1</i> , <i>TGFBR2</i> , <i>MYH11</i> , <i>MYLK</i>)
Vascular Ehlers-Danlos syndrome (vEDS) (<i>COL3A1</i>)
Aneurysms-osteoarthritis syndrome (<i>SMAD3</i>)
<i>TGFBR2</i> mutations
Congenital diseases/syndromes
Coarctation of the aorta
Turner syndrome (TS)
Tetralogy of Fallot (TOF)
Atherosclerosis
Penetrating atherosclerotic ulcer (PAU)
Trauma, blunt or iatrogenic
Catheter/guidewire
Intra-aortic balloon pump
Aortic/vascular surgery
Motor vehicle accident
Coronary artery bypass grafting (CABG)/aortic valve replacement (AVR)
Thoracic endovascular aneurysm repair (TEVAR), endovascular stent
Cocaine/methamphetamine use
Inflammatory/infectious diseases
Giant cell arteritis
Takayasu arteritis
Behçet disease
Aortitis
Syphilis
Pregnancy (with underlying aortopathy)
Weightlifting (usually with underlying aortopathy)

Genetically triggered aortic syndromes, congenital heart diseases, atherosclerosis, inflammatory vascular diseases, cocaine use, and iatrogenic causes are also risk factors for aortic dissection. CMD commonly underlies aortic dissection (see Fig. e57-1), as well as several genetically triggered disorders of connective tissue, including MFS, LDS, familial TAAD syndromes, and vEDS; it is also common in patients with a congenital BAV (see Table 57-2). Excessive signaling in the TGF- β pathway and abnormalities in function of the SMC contractile element may underlie certain aortic aneurysm syndromes.¹² Patients with MFS are at high risk for aortic root aneurysm and especially for type A aortic dissection. Despite being present in only approximately 1 in 5000 individuals, MFS accounts for approximately 5% of all aortic dissections and a significant proportion of aortic dissection in young patients.^{14,40} Common genetic variants at 15q21.1 that probably act via *FBNI* are also associated with sporadic TAAD.³⁸ CMD may occur in many other conditions affecting the aorta, including aging and hypertension. Whether the preponderance of cases of aortic dissection will eventually be related to an underlying genetic trigger is yet unknown and the subject of active investigation.

When a young patient with aortic dissection is encountered, one must consider genetically triggered disorders (MFS, LDS, vEDS, familial TAAD, BAV, aneurysm-osteoarthritis syndrome [*SMAD3* mutations], *TGFBR2* mutations, TS), cocaine use, coarctation of the aorta, and previous AVR. A BAV is an often underrecognized risk factor for ascending aortic aneurysm and dissection and occurs in 5% to 7% of patients with aortic dissections (even more commonly with ascending dissections in the young).¹⁸ Aortic dissection may occur in the setting of a BAV that functions “normally” and, importantly, may occur years after BAV replacement.¹⁸ Other disorders associated with aneurysm and dissection include Noonan syndrome, unicuspid aortic valve, supraaortic stenosis, aberrant right subclavian artery (Kommerell diverticulum), right-sided aortic arch, polycystic kidney disease, and Alport syndrome (in males).¹⁴

Rarely, aortic dissection complicates aortitis, particularly giant cell arteritis. Nonspecific aortitis, Takayasu arteritis, and Behçet disease

have all been associated with aortic dissection. Syphilitic aortitis is a rare cause of dissection. Cocaine abuse (particularly crack cocaine) accounts for less than 1% of cases of aortic dissection. Underlying elastic medial abnormalities and the severe shear forces related to hypertension and tachycardia may play a role. Aortic dissection is also reported with intense weightlifting, but generally in the setting of an underlying aortopathy.

Aortic dissection is rarely described during late pregnancy or in the early postpartum period.⁴¹ The relationship between pregnancy and aortic dissection is difficult to reconcile based on hemodynamic factors alone, and hormonal changes in aortic wall composition may occur during pregnancy. Although most patients with pregnancy-related aortic dissection have an underlying aortopathy or genetically triggered aneurysm syndrome, the syndrome is not diagnosed in many until after dissection occurs.^{34,36} Women with aortopathy from many disorders, including MFS, LDS, familial TAAD, vEDS, TS, and BAV with a dilated aorta, are at increased risk for acute aortic dissection during pregnancy. In MFS, the risk for type A dissection is greatest when the aortic root is enlarged and has been estimated to be 1% when the aortic diameter is less than 40 mm and 10% in high-risk patients (aortic diameter >40 mm, rapid dilation, or previous dissection of the aorta).⁴⁰

Blunt aortic trauma usually leads to localized tears or periaortic or frank aortic transection and only rarely causes classic aortic dissection. Iatrogenic trauma accounts for approximately 5% of aortic dissections.^{39,42} Intra-arterial catheterization, stent placement, and insertion of intra-aortic balloon pumps may induce aortic dissection because of disruption of the intima. Cardiac surgery entails a very small risk (0.16%) for acute aortic dissection that is related to aortic cannulation, crossclamps, aortic anastomosis, and retrograde dissection as a result of femoral cannulation. Iatrogenic type A dissection is most commonly related to cardiac surgery, with the dissection generally originating at the site of arterial inflow, and is associated with a high mortality rate.⁴² Aortic dissection may occur late (months to years) after cardiac surgery, with those undergoing AVR or with a previous aneurysm or dissection having the highest risk. Persistent abnormalities of the aortic wall, such as the aortopathy seen with a BAV, and injuries to the aortic wall related to crossclamping, suture lines, or cannulation account for the increased risk for subsequent dissection. Retrograde ascending aortic dissection occurs in approximately 1% to 2% of patients undergoing TEVAR for acute or chronic type B aortic dissection and is associated with a significant mortality rate.⁴³

Individuals with TAA are at risk for aortic dissection, with risk for dissection and rupture increasing as aneurysm size increases. However, many aortic dissections occur in patients with aortic dimensions that are not severely dilated. Of type A aortic dissections in the IRAD, aortic diameter averaged 5.3 cm, with approximately 60% having aortic diameters smaller than 5.5 cm and 40% having aortic diameters smaller than 5.0 cm.⁴⁴ In a series of non-MFS patients with TAVs and acute type A aortic dissection, at the time of dissection 62% of patients had aortic diameters smaller than 5.5 cm, 42% had aortic diameters smaller than 5 cm, and more than 20% had aortic diameters smaller than 4.5 cm.⁴⁵ In addition to aortic size, age, sex, body size, and rate of aortic growth, mechanical and hemodynamic factors also play a role. The mechanisms responsible for individual susceptibility to acute dissection at a certain aortic size are poorly understood.

Clinical Manifestations
Symptoms

The symptoms of aortic dissection can be variable and may mimic those of more common conditions, thus emphasizing the importance of a high index of suspicion. The most common symptom of acute aortic dissection is pain, which occurs in up to 96% of cases.³⁹ The pain is described as severe in approximately 90% of patients and usually of sudden onset, with maximum intensity occurring at its inception. The pain may be accompanied by a “sense of doom.” The quality of the pain is most commonly described as “sharp,” “severe,”

or “stabbing,” and adjectives such as “tearing” or “ripping” are used less commonly.^{14,39} Symptoms highly suggestive of aortic dissection, such as a feeling of being “stabbed in the chest with a knife” or “hit in the back with a baseball bat,” may be reported, but some aortic dissections are characterized by chest burning, pressure, or pleuritic pain. The pain may abate or lessen, which makes diagnosis even more challenging. In some patients the symptoms related to a complication of the dissection (such as syncope, heart failure, or stroke) dominate, and the pain is not mentioned or is downplayed.

The pain of acute aortic dissection is migratory in approximately 17% of cases and tends to follow the path of the dissection through the aorta.³⁹ The pain of dissection may radiate from the chest to the back, or vice versa. Pain in the neck, throat, jaw, or head predicts involvement of the ascending aorta (and often the great vessels), whereas pain in the back, abdomen, or lower extremities usually indicates descending aortic involvement.

Other clinical features at initial evaluation that occur with or without associated chest pain may include congestive heart failure (7%), syncope (9%), acute stroke (6%), acute MI, ischemic peripheral neuropathy, paraplegia, and cardiac arrest or sudden death.³⁹ Acute congestive heart failure related to ascending dissection generally results from acute severe aortic regurgitation. Syncope is much more common in patients with ascending aortic dissection and is usually associated with hemopericardium, rupture, or stroke. Patients with aortic dissection infrequently have predominantly abdominal pain, which may lead to delays in diagnosis and an increased mortality rate. Painless aortic dissection occurs in 6% of patients and is more common in those with diabetes, previous aortic aneurysm, and prior cardiac surgery.³⁹ “Painless” aortic dissections are complicated by syncope in approximately 33%, by heart failure in 20%, and by stroke in 11% and are associated with an increased mortality rate.¹⁴

Physical Findings

Findings on physical examination and organ system complications in patients with acute aortic dissection are highly variable and range from virtually unremarkable to full cardiac arrest secondary to hemopericardium or rupture. The findings may demonstrate complications related to the dissection, such as aortic regurgitation, abnormal peripheral pulses, stroke, or heart failure (Table 57-6). The presence of these findings must heighten clinical suspicion for aortic dissection,¹⁴ but their absence does not exclude dissection and should not dissuade pursuit of the diagnosis when suspected. Hypertension occurs in approximately 70% of patients with acute aortic dissection. Although most patients with type B dissection are hypertensive, many with type A dissection are normotensive or hypotensive on initial evaluation.³⁹ Recent series of type A aortic dissection report that at hospital arrival, 50% of patients are hemodynamically unstable, 25% have a neurologic deficit, 20% have tamponade, and 6% have required cardiopulmonary resuscitation.⁴⁶ Hypotension complicating acute dissection may result from cardiac tamponade, acute aortic rupture, or heart failure related to acute severe aortic regurgitation.

The physical findings most typically associated with aortic dissection—pulse deficits, aortic regurgitation, and neurologic manifestations—are more characteristic of ascending than descending dissection. In the IRAD, a pulse deficit was reported in 19% of type A dissections and in only 9% of type B dissections. Others have reported pulse deficits in 31% of cases.¹⁴ The vascular insufficiency related to aortic dissection may result from the dissection flap propagating into a branch artery and thereby leading to compression of the true lumen by the distended false lumen and limiting blood flow (static obstruction) (Fig. 57-13), or it may result from obstruction of flow into the orifice of the artery by a prolapsing intimal flap (dynamic obstruction). Other causes of end-organ ischemia include postobstructive arterial thrombosis, arterial embolism, compression of an artery by an expanding false lumen, or a low-cardiac output state.¹⁴

Aortic regurgitation is an important diagnostic feature of type A dissection and occurs in 41% to 76% of patients with type A dissection (Fig. 57-14).^{14,39} The murmur of aortic regurgitation varies in intensity, depending on blood pressure and the degree of heart failure, and may be inaudible in some cases. Potential mechanisms of aortic

TABLE 57-6 Organ System Complications of Acute Aortic Dissection

Cardiovascular	Cardiac arrest Syncope Aortic regurgitation Congestive heart failure Coronary ischemia Myocardial infarction Cardiac tamponade Pericarditis
Pulmonary	Pleural effusion Hemothorax Hemoptysis (from an aortotracheal or bronchial fistula)
Renal	Acute renal failure Renovascular hypertension Renal ischemia or infarction
Neurologic	Stroke Transient ischemic attack Paraparesis or paraplegia Encephalopathy Coma Spinal cord syndrome Ischemic neuropathy
Gastrointestinal	Mesenteric ischemia or infarction Pancreatitis Hemorrhage (from an aortoenteric fistula)
Peripheral vascular	Upper or lower extremity ischemia
Systemic	Fever

FIGURE 57-13 Contrast-enhanced CT scan demonstrating malperfusion of the right kidney (RK) because of acute aortic dissection. The dissection flap involves the right renal artery (arrow). The left kidney (LK) demonstrates normal perfusion and opacification, whereas the RK has poor perfusion with contrast material, consistent with malperfusion.

regurgitation in the setting of type A aortic dissection include (1) incomplete coaptation of the aortic leaflets because of concurrent dilation of the aortic root and annulus or because of acute aortic dilation from an expanding false lumen leading to central aortic regurgitation, (2) aortic leaflet prolapse caused by the dissection flap

FIGURE 57-14 Aortic regurgitation complicating acute type A aortic dissection. The dissection flap distorts the normal aortic leaflet alignment, thereby leading to malcoaptation of the aortic valve and subsequent aortic regurgitation. In this example the dissection flap extends into the ostium of the right coronary artery (arrow).

propagating into the aortic leaflets or commissures or by distortion of proper leaflet alignment by an asymmetric dissection flap leading to eccentric aortic regurgitation (Fig. 57-14) (Videos 57-4 and 57-5), (3) an extensive or circumferential dehiscing intimal flap prolapsing into the left ventricular outflow tract during diastole and interfering with valve coaptation (Fig. e57-6, Videos 57-6 and 57-7), and (4) preexisting aortic regurgitation related to the underlying aortic root aneurysm or BAV.¹⁴

Neurologic manifestations occur in 17% to 40% of patients with aortic dissection and are more common with type A dissections.⁴⁷ Up to 50% of dissection-related neurologic symptoms are transient.¹⁴ Syncope, “painless” aortic dissection, and dissections with predominantly neurologic symptoms may lead to difficulty or delay in diagnosis. Neurologic syndromes include persistent or transient ischemic stroke, spinal cord ischemia, ischemic neuropathy, and hypoxic encephalopathy and are related to malperfusion of one or more branches supplying the brain, spinal cord, or peripheral nerves (Table e57-2).⁴⁸ Ischemic stroke occurs in approximately 6% of patients with ascending dissections and is more commonly right sided hemispheric (because the left-sided arch vessels are more susceptible to the advancing false lumen).^{39,48} Syncope is relatively common in aortic dissection, with 9% to 13% of patients being affected, and may occur in the absence of pain or other neurologic findings.^{14,39} Syncope may be related to acute hypotension (caused by cardiac tamponade, severe aortic regurgitation, or aortic rupture), obstruction of a cerebral vessel, or activation of cerebral baroreceptors and carries an increased mortality rate.¹⁴ Less common neurologic manifestations of dissection include seizures, transient global amnesia, ischemic neuropathy, disturbances in consciousness and coma, and paraparesis or paraplegia related to spinal cord ischemia. Some studies have failed to identify brain malperfusion as an independent risk factor for an adverse outcome after surgical repair,^{14,39,48} whereas others report that cerebral malperfusion is associated with poor outcomes.⁴⁹

Acute MI related to involvement of the dissection flap in the ostium of a coronary artery occurs in 1% to 2% of patients with acute type A aortic dissection. It most commonly involves the right coronary artery (Fig. 57-14) and leads to acute inferior MI. Aortic dissection may not be a suspected cause of acute MI, and misdiagnosis of dissection in this setting may lead to dire consequences because of inappropriate therapy and delays in treatment. Considering aortic dissection in the differential diagnosis of patients with acute infarction, especially when their risk factors, symptoms, or findings on examination are compatible with this diagnosis, is important. If coronary angiography is performed in a patient with ST-segment elevation MI and no culprit lesion is found, aortic dissection should be excluded.¹⁴

Aortic dissection may extend into the abdominal aorta and result in vascular complications involving one or more branch vessels. Renal artery involvement occurs in at least 5% to 10% of patients and may lead to renal ischemia, infarction, or renal insufficiency or refractory hypertension (see Fig. 57-13). Mesenteric ischemia or infarction, complications associated with a high level of morbidity and mortality, occur in approximately 5% patients with aortic dissection. A high index of suspicion is required for this diagnosis, and identifying and correcting visceral malperfusion may be associated with improved outcomes.⁵⁰ Acute limb ischemia and malperfusion syndromes are associated with extensive and severe dissection and a higher mortality rate.⁴⁹

Aortic dissection may lead to a left-sided pleural effusion in approximately 20% of cases, usually related to an inflammatory response. Acute hemothorax may occur as a result of rupture, contained rupture, or leakage associated with aortic dissection. Type A aortic dissection may be accompanied by acute pericarditis, including characteristic electrocardiographic changes. More commonly, a bland pericardial effusion occurs. Acute cardiac tamponade as a result of rupture with hemopericardium complicates approximately 9% of ascending dissections and has been related to poorer outcomes.¹⁴ Isolated abdominal aortic dissection is rare (≈1% of dissections) and associated with an existing AAA or an iatrogenic cause. Rare clinical manifestations of aortic dissection include hoarseness, upper airway obstruction, dysphagia, superior vena cava syndrome, pulsatile neck or abdominal masses, hematemesis (from rupture into the esophagus), hemoptysis (from rupture into the trachea or bronchus), ischemic pancreatitis, and unexplained fever (from the inflammatory reaction).

Aortic dissection may not be considered during the evaluation of a patient with chest, back, or abdominal pain. Dissection may mimic many other more common disorders. In some cases the diagnosis is suspected immediately at initial encounter, whereas at other times the diagnosis is made when imaging studies are performed for another reason. Thus one of the most important factors in making the diagnosis of aortic dissection is a high index of suspicion.

Laboratory Findings

The chest radiograph may be the first clue to the diagnosis of aortic dissection (Fig. e57-7), but the findings are nonspecific, subject to interobserver variability, and in many cases, completely normal. The dissected aorta may not be dilated and its image may not be displaced or widened on chest radiographs. The most common abnormality seen on a chest radiograph in a patient with aortic dissection is an abnormal aortic contour or widening of the aortic silhouette, which appears in 80% to 90% of cases (83% of type A; 72% of type B).³⁹ Nonspecific widening of the superior mediastinum may be present. If calcification of the aortic knob occurs, one may detect separation of the intimal calcification from the outer aortic soft tissue border by more than 0.5 to 1.0 cm—the “calcium sign” (Fig. e57-8). Pleural effusions occur in approximately 20% of dissections. Even though most patients with aortic dissection will have abnormal findings on a chest radiograph, 12% to 15% have chest radiographs with normal findings. Thus normal chest radiograph results cannot exclude the presence of an aortic dissection.

The electrocardiographic findings in patients with aortic dissection are nonspecific but may indicate acute complications such as myocardial ischemia or infarction related to coronary artery

FIGURE e57-6 TEE of an acute type A aortic dissection with a circumferential intimal flap (*arrow*) prolapsing across the aortic valve into the left ventricular outflow tract and leading to severe aortic regurgitation.

TABLE e57-2 Neurologic Manifestations of Aortic Dissection

MECHANISM AND LOCATION	MANIFESTATIONS
Brain	
Extension of dissection to aortic arch vessels	Transient ischemic attack
Reduced cerebral perfusion secondary to hypotension	Stroke
Nerve compression by an enlarging false lumen	Transient global amnesia Hypoxic encephalopathy Horner syndrome Seizure Coma
Spinal Cord	
Spinal cord ischemia secondary to obstruction of spinal arteries	Paraparesis Paraplegia Anterior spinal cord syndrome Brown-Sequard syndrome Progressive myelopathy Transient spinal cord ischemia
Peripheral Nerve	
Obstruction of the vasa nervorum	Ischemic neuropathy (paraparesis, polyneuropathy, mononeuropathy)
Compression of a nerve by an enlarging false lumen	Ischemic plexopathy Nerve compression syndrome

involvement or low-voltage QRS complexes (or rarely, acute pericarditis) related to hemopericardium. Acute MI occurs in 1% to 2% of patients with type A dissections. The presence of acute coronary ischemia is particularly dangerous because it may lead the clinician away from the evaluation of dissection.

Biomarkers. Reliable biomarkers for the diagnosis or exclusion of acute aortic dissection have aroused great interest. Release of smooth muscle proteins, soluble elastin fragments, myosin heavy chain and the BB isoform of creatine kinase, and TGF- β occurs after aortic dissection.⁵¹ These markers have limited usefulness because of sensitivity, specificity, or time delay and are not currently available for clinical use.

Patients with acute aortic dissection have elevated D-dimer levels.^{14,51} A D-dimer level higher than 1600 ng/mL within the first 6 hours after the initial evaluation was found to have a positive likelihood ratio of 12.8, thus suggesting that this test may be useful in identifying patients with a high probability of having acute aortic dissection.⁵¹ In patients seen within the first 24 hours of onset, a D-dimer level lower than 500 ng/mL had a negative likelihood ratio of 0.07 and a negative predictive value of 95%.⁵¹ In a meta-analysis of 349 patients with proven aortic dissection, the sensitivity of the D-dimer assay was 94%, and its specificity was 40% to 100%.¹⁴ Even though the D-dimer level may assist clinicians in their diagnostic approach, normal D-dimer levels have been associated with aortic dissection and a thrombosed false lumen, as well as with aortic IMH and PAU.¹⁴ Additionally, patients may initially be seen longer than 24 hours after symptom onset, which affects D-dimer levels. Although a negative D-dimer result in low-suspicion patients may be useful, the negative likelihood ratio provided by the D-dimer assay is not sufficient in high-risk individuals and cannot “rule out” the disease in these patients.¹⁴ The recent thoracic aortic disease guideline writing committee did not recommend D-dimer screening for all patients being evaluated for aortic dissection.¹⁴ More studies are required to determine the sensitivity and specificity of this assay in diagnosing acute aortic syndromes.

Diagnostic Techniques

When aortic dissection is suspected, quick and accurate confirmation of the diagnosis is important. Diagnostic methods available to diagnose aortic dissection include contrast-enhanced CT, MRI, TTE and TEE, and aortography. TEE, helical CT, and MRI have very high diagnostic accuracy for suspected aortic dissection.¹⁴ Each modality has advantages and disadvantages with respect to diagnostic ability, speed, convenience, and risk. The choice of imaging study depends on the availability and expertise in the individual institution, with contrast-enhanced CT and TEE being the most commonly performed. Many patients undergo multiple studies. If the probability of dissection is very high and initial testing is negative or nondiagnostic, a second diagnostic test should be performed. When comparing imaging modalities, one must consider the diagnostic information needed (**Table e57-3**). Besides diagnosing the type and location of dissection, additional useful information includes anatomic features and complications related to the dissection, including its extent, entry sites, and reentry sites; patency of the false lumen; involvement of branch vessels; severity of aortic regurgitation; hemopericardium; coronary artery involvement; malperfusion; and rupture or leaking.

Computed Tomography

Contrast-enhanced CT is the modality most commonly used for evaluating aortic dissection and is best performed with an electrocardiographically gated, multidetector scanner, which may eliminate aortic pulsation motion artifacts. On CT, aortic dissection is diagnosed by the presence of two distinct lumina with a visible intimal flap, which is seen in most cases, or by detection of two lumina by their differing rates of opacification with contrast material (see **Figs. 57-4, 57-10, 57-12, 57-13**, and **e57-2**). If the false lumen is completely thrombosed, it demonstrates low attenuation. Spiral (helical) contrast-enhanced CT allows three-dimensional reconstruction for evaluation of the dissection and branch vessels and is critical for decision making—especially when planning endovascular repair. Contrast-enhanced CT is highly accurate in diagnosing aortic dissection, with a sensitivity and specificity of 98% to 100%.¹⁴

CT requires intravenous contrast material, and without contrast enhancement, aortic dissection may go undetected (**Fig. e57-9**). CT can also help identify the presence of thrombus (partial or complete) in the false lumen and assist in detecting hemopericardium, periaortic hematoma, aortic rupture, and branch vessel involvement and blood supply from the true and false lumina. Major limitations of CT include an inability to evaluate the coronary arteries and aortic valve reliably, motion artifact related to cardiac movement, streak artifact related to implanted devices, and complications associated with the use of contrast agents, especially nephropathy (see **Chapter 88**).

Magnetic Resonance Imaging

MRI is highly accurate in evaluating aortic dissection—its accuracy being similar to or higher than that of CT—and does not require intravenous iodinated contrast material or ionizing radiation (**Fig. e57-10**). MRI permits multiplanar imaging with three-dimensional reconstruction and cine-MRI for visualization of blood flow, differentiation of slow flow and clot, and detection of aortic regurgitation. Most MRI protocols can assess branch vessel morphology when combined with contrast-enhanced (gadolinium) MRA. MRI may detect pericardial effusion, aortic rupture, entry points, and exit points with a high level of accuracy; MRA may detect and quantify aortic regurgitation. MRI has important limitations, however, in evaluating acute aortic dissection. First, it is contraindicated in patients with certain implantable devices (pacemaker, defibrillator) and other metallic implants. Additionally, MRI has limited availability on an emergency basis, and more time is needed to acquire images than with CT. Thus MRI is infrequently used as the initial test for evaluation of acute dissection, but given its imaging detail and lack of ionizing radiation, it is particularly attractive for the long-term follow-up of aortic dissection.

Echocardiography

The echocardiographic finding considered diagnostic of aortic dissection is the presence of an undulating intimal flap within the aortic lumen that separates the true and false channels (Videos 57-8 to 57-12; also see Videos 57-4 and 57-6). Reverberations and other artifacts can cause linear echodensities within the aortic lumen that mimic aortic dissection. Differing from such artifacts, a dissection flap has motion independent of the surrounding structures and is contained within the aortic lumen.¹⁴ Color-flow Doppler ultrasound demonstrates differential flow in the two lumina. In cases in which the false lumen is thrombosed, displacement of intimal calcification or thickening of the aortic wall may suggest aortic dissection.

Transthoracic Echocardiography

TTE has a sensitivity of 77% to 80% and a specificity of 93% to 96% for the identification of proximal aortic dissection, but it is much less sensitive (31% to 55%) than other modalities for the diagnosis of distal aortic dissection (**Fig. e57-11**; also see Videos 57-10 to 57-12).¹⁴ Harmonic imaging and contrast enhancement have increased the sensitivity and specificity of TTE for the diagnosis of type A aortic dissection.⁵² Because of its reduced sensitivity in the setting of suspected aortic dissection, negative findings on TTE do not exclude acute aortic dissection, but certain clues, including a dilated aorta, aortic regurgitation, or pericardial effusion, may raise suspicion for acute aortic dissection.⁵² TTE may also demonstrate an intimal flap, a thickened aortic wall, or cardiac tamponade (Video 57-13).

Transesophageal Echocardiography

TEE is highly accurate in the evaluation and diagnosis of acute aortic dissection (sensitivity, \approx 98%; specificity, \approx 95%), but its accuracy is operator dependent⁵² (**Fig. 57-14**; also see Videos 57-4 to 57-9). Linear reverberation artifacts are common, particularly in a dilated ascending aorta, and may be mistaken for a dissection flap.⁵² TEE may not completely visualize the distal ascending aorta and proximal aortic arch, but it interrogates the remaining thoracic aortic segments well. TEE may visualize the intimal tear in 75% to 100% of cases and may differentiate the true and false lumina (**Fig. e57-12** and Video 57-14; also see Video 57-4).⁵² Features of the true lumen on TEE include a

smaller lumen, systolic expansion, systolic anterograde flow, communication from the true to the false lumen in systole, and early and fast contrast-enhanced echocardiographic flow.⁵² TEE is 100% sensitive in detecting aortic regurgitation complicating dissection and may define its mechanism (Fig. 57-15; also see Videos 57-4 to 57-7). Additionally, TEE provides information about wall motion, left ventricular function, and pericardial effusion. TEE may visualize the proximal coronary arteries and indicate whether they are involved in the dissection.

Aortography

Even though dissection is occasionally diagnosed in the cardiac catheterization laboratory when the initial diagnosis was inadvertently considered to be an acute coronary syndrome (Videos 57-15 to 57-17), aortography is rarely used for the initial diagnosis of acute aortic dissection. The diagnosis of dissection by aortography is based on imaging the two lumina or an intimal flap (Figs. e57-13 and e57-14, see Video 57-17). Other features may include an undulating deformation of the aortic lumen, aortic wall thickening, branch vessel involvement, and aortic regurgitation. When compared with other imaging modalities, aortography has less accuracy in diagnosing aortic dissection (sensitivity, 90%; specificity, 94%). A false-negative aortogram may result from thrombosis of the false lumen, from equal opacification of both the true and false lumina, and from IMH.

Selecting an Imaging Modality

Because of its availability on an emergency basis, contrast-enhanced CT is usually the first choice for the diagnosis of aortic dissection.

The risk for contrast-induced nephropathy often complicates the decision about which test to perform when TEE or MRI is unavailable. Clinicians should remember that non-contrast-enhanced CT might fail to diagnose aortic dissection (see Fig. e57-9). Non-contrast-enhanced MRA may be able to diagnose aortic dissection when gadolinium contrast is contraindicated. If TEE or MRI is not available on an urgent basis, one must weigh the risks associated with intravenous contrast material versus the potential fatal consequences of failing to diagnose aortic dissection. TTE may occasionally be used to diagnose acute ascending aortic dissection, and if there is any concern about the time delay in performing other imaging modalities, emergency bedside TTE may prove very useful. Negative findings on TTE, however, do not exclude aortic dissection. The diagnostic approach to a patient with suspected aortic dissection must be based on each institution's available resources and expertise and the rapidity and accuracy with which they can be performed.

The Role of Coronary Angiography

Routine coronary angiography is not recommended before surgery for acute type A aortic dissection because of concern about delay in emergency surgery.^{14,53} Coronary angiography in patients with acute type A aortic dissection has not been associated with improvements in clinical outcomes.⁵³

Coronary artery involvement in aortic dissection may be due to various causes. The aortic dissection flap may obstruct the orifice of the coronary artery and lead to coronary ischemia or infarction (see Videos 57-15 and 57-16). Additionally, the dissection flap may propagate down the coronary artery and result in obstruction of flow (see Fig. 57-14). At present, preoperative catheterization is only infrequently performed before emergency repair of ascending aortic dissection—in less than 10% of patients.⁵³ Importantly, many cardiac catheterizations in this series may have been performed before acute aortic dissection was diagnosed.⁵³ Besides the time delay incurred, coronary angiography may be technically difficult in the setting of dissection. Arterial access may fail to gain entry into the true lumen, and injury to the aorta from the catheter or guidewire may cause extension of the dissection or perforation of the aorta. Further evaluation for coronary artery disease before aortic dissection surgery may be indicated in some patients—including individuals with a history of coronary disease or previous coronary artery bypass surgery and those with acute ischemic electrocardiographic changes. In patients undergoing surgery for acute type A dissection, coronary artery involvement by the dissection can most often be corrected intraoperatively, and angiography is not required. Candidates for preoperative cardiac catheterization must be hemodynamically stable. Cardiac tamponade and aortic rupture are contraindications to coronary angiography. Experience with intraoperative coronary angiography for aortic dissection is very limited.

Evaluation and Management Algorithms

The 2010 guidelines for thoracic aortic disease provide an algorithm for the management of patients whose signs and symptoms are concerning for the possibility of acute aortic dissection (Fig. 57-16).^{14,54} Performance of a focused bedside risk assessment determines whether the patient has any of three high-risk features: (1) *high-risk condition* (MFS or related connective tissue disease, family history of aortic disease, known aortic valve disease [such as BAV], recent aortic manipulation, or known TAA); (2) *high-risk pain features*, including chest, back, or abdominal pain described as abrupt in onset, severe in intensity, and of ripping/tearing/sharp or stabbing quality; and (3) *high-risk examination features*, including perfusion deficit (pulse deficit, blood pressure differential, focal neurologic deficit), murmur of aortic regurgitation, or hypotension. The presence of two or more high-risk features strongly suggests aortic dissection. Patients considered highly likely to have acute aortic dissection undergo emergency surgical consultation and expedited imaging. Patients whose features suggest aortic dissection and who do not have an alternative diagnosis require expedited imaging. Those with lower-risk profiles are evaluated for alternative diagnoses, but when

FIGURE e57-13 Left oblique view of an aortogram demonstrating proximal aortic dissection and its associated cardiovascular complications. The true lumen (T) and false lumen (F) are separated by the intimal flap (I), which is faintly visible as a radiolucent line following the contour of the pigtail catheter. The true lumen is better opacified than the false lumen, and the two planes of the intimal flap can be distinguished (arrows). The branch vessels are opacified, along with marked narrowing of the right carotid artery (CA), which suggests that its lumen is compromised by the dissection. (From Isselbacher EM: *Aortic dissection*. In Creager MA [ed]: *Atlas of Vascular Disease*. 2nd ed. Philadelphia, Current Medicine, 2003.)

VIDEO 57-15

Coronary angiogram of a patient with acute chest pain and ST-segment depressions. A left coronary artery injection demonstrates mild external compression and narrowing of the left main coronary artery (because of an aortic dissection flap).

VIDEO 57-16

Left main coronary injection of the same patient with acute type A aortic dissection depicted in Video 57-14. Note the faint dye staining of the left main coronary artery because of stasis of flow in the false channel involving the left main coronary artery.

VIDEO 57-17

Aortogram in the patient depicted in Videos 57-14 and 57-15 demonstrating acute type A dissection. Note the dilated aortic root. The pigtail catheter is within the true lumen of the aorta. The less opacified false lumen is present in the left sinus of Valsalva and along the greater or outer curvature of the ascending aorta.

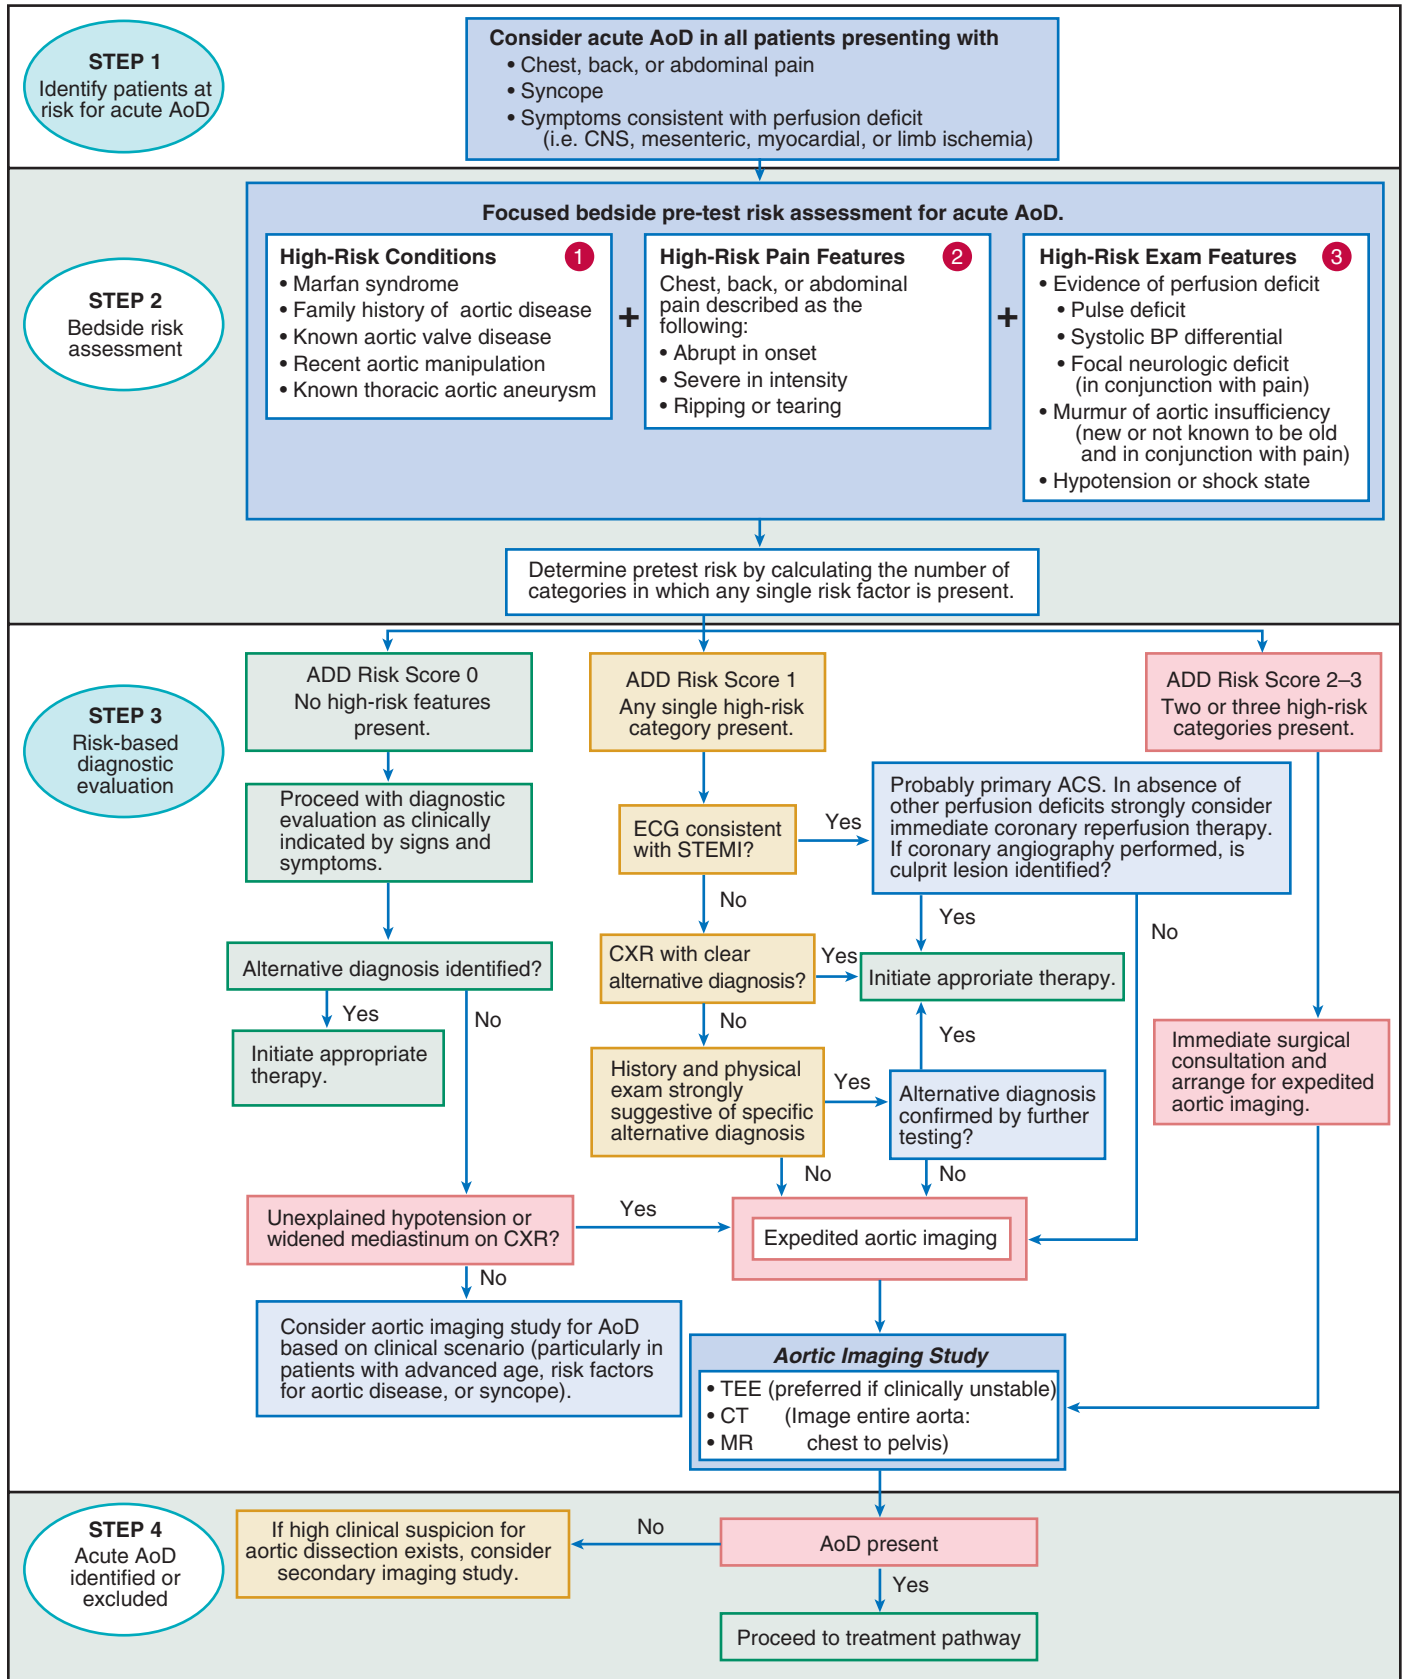

FIGURE 57-16 Evaluation pathway for aortic dissection (AoD). ACS = acute coronary syndrome; ADD = aortic dissection detection; BP = blood pressure; CNS = central nervous system; CXR, chest x-ray; STEMI = ST-segment elevation myocardial infarction. (Modified from 2010 American College of Cardiology/American Heart Association thoracic aortic disease guidelines.¹⁴ From Rogers AM, Hermann LK, Boohar AM, et al: Sensitivity of the aortic dissection detection risk score, a novel guideline-based tool for identification of acute aortic dissection at initial presentation: Results from the International Registry of Acute Aortic Dissection. *Circulation* 123:2213, 2011.)

none are considered likely or are confirmed, aortic imaging is recommended. This tool has been demonstrated to be highly sensitive for the detection of aortic dissection when applied to patients known to have dissection in the IRAD database.⁵⁴ Further investigation is needed to prospectively validate the accuracy of this risk score and in particular to assess the specificity of this algorithm for patients with chest, back, or abdominal pain.⁵⁴ Atypical manifestations, female sex, and previous cardiac surgery are associated with delays in diagnosis.⁵⁵

Management

The guidelines for thoracic aortic disease suggest a management pathway for patients with acute aortic dissection (**Fig. 57-17**).¹⁴ Initial medical management includes stabilizing the patient, controlling pain, lowering blood pressure, and reducing the rate of rise in the force (dP/dt) of left ventricular contraction with beta blockers. These measures should commence immediately while the patient is undergoing diagnostic evaluation. Lowering blood pressure may help prevent further propagation of the dissection and lessen the risk for aortic rupture. Aortic dissection has high mortality. In the IRAD, medical management of acute type A dissection had a mortality of 20% in the first day and 30% by 48 hours.³⁹ The time-dependent risk for mortality with acute type A dissection after hospitalization was estimated to be 15% to 30% in the first 24 hours of admission, 10% to 20% between 24 and 48 hours, 10% to 20% between 2 and 5 days, and 1% per day between 5 and 30 days.²⁸ Emergency surgery leads to improved survival in patients with acute type A dissections, whereas initial medical therapy is recommended for acute type B dissections. Patients with acute aortic dissection require urgent multidisciplinary evaluation and management. Emergency transfer to a tertiary medical center with access to cardiovascular surgery, vascular surgery, interventional radiology, and cardiology is recommended for patients with acute dissection.¹⁴

Surgical therapy for type A aortic dissection has dramatically improved the survival of patients with this often-lethal condition. Surgical therapy aims to treat or prevent the common complications of dissection, including cardiac tamponade, aortic regurgitation, aortic rupture, stroke, and visceral ischemia. The immediate surgical goals are to excise the intimal tear; to obliterate the false channel by oversewing the edges of the aorta; and to reconstitute the aorta, directly or more commonly, with placement of an interposition graft. In type A dissection, aortic regurgitation is also treated by resuspension of the aortic valve leaflets or by prosthetic AVR.

Blood Pressure Reduction

Reduction of systolic blood pressure to levels of approximately 100 to 120 mm Hg or the lowest level appropriate for adequate perfusion is recommended.¹⁴ Beta blockers should be administered even if the patient does not have systolic hypertension, with a goal of attaining a heart rate of 60 beats/min or lower. For rapid administration of agents to reduce the rate of rise in ventricular force (dP/dt) and stress on the aorta, intravenous beta blockers should be given. The short-acting beta blocker esmolol is given as an initial bolus of 500 µg/kg and then as a continuous infusion of 50 to 200 µg/kg/min. Labetolol is an alpha- and beta-adrenergic-blocking agent and may be administered intravenously in the acute setting or orally. Labetolol is given at an initial dose of 20 mg intravenously over a 2-minute period and then at a dose of 40 to 80 mg intravenously every 15 minutes (maximum dose, 300 mg) until the desired response is achieved; it is then administered by continuous intravenous infusion at a rate of 2 to 10 mg/min. Propranolol or metoprolol may be also used intravenously or orally for acute aortic dissection.

When beta blockers are contraindicated, one may consider the calcium channel-blocking agents verapamil or diltiazem. These drugs have both negative inotropic and chronotropic effects and may be administered intravenously. Intravenous diltiazem is dosed at 0.25 mg/kg over a 2-minute period and then continued as an infusion at a rate of 5 to 15 mg/hr, depending on the effect.

Sodium nitroprusside leads to rapid reduction of blood pressure, but it also may result in an increase in dP/dt—thus it must be used

together with a beta blocker in the setting of acute aortic dissection. Sodium nitroprusside is initiated at a dose of 20 µg/min, with up titration to 0.5 to 5 µg/kg/min as required. Frequently, multiple agents are required for adequate control of blood pressure and the heart rate in patients with acute aortic dissection. Intravenous ACE inhibitors such as enalaprilat and intravenous nitroglycerin may be useful.

Refractory hypertension in patients with acute dissection may have several explanations. First, the patient may have underlying severe hypertension and may have omitted medications, with subsequent “rebound” (especially with beta blockers or clonidine). Uncontrolled pain may exacerbate hypertension. Additionally, acute cocaine (or methamphetamine) use may lead to tachycardia and hypertension. Finally, the patient may have renal artery involvement by the dissection flap leading to hypertension (see **Fig. 57-12**). This complication may require endovascular therapy.

When a patient with suspected aortic dissection has significant hypotension, rapid volume expansion should be considered given the possible presence of cardiac tamponade or aortic rupture with hemorrhage into the mediastinum, pleural space, or abdomen.

Management of Cardiac Tamponade

Cardiac tamponade, which occurs in 8% to 31% of acute type A dissections, is one of the most common mechanisms of death in patients with dissection^{56,57} (**Fig. e57-15**; also see Video 57-13). Patients with tamponade more likely have hypotension, syncope, or altered mental status. Patients with cardiac tamponade have twice as high an in-hospital mortality rate as do those without tamponade (54% versus 25%).⁵⁶ Pericardiocentesis for acute hemopericardium in patients with dissection can result in recurrent bleeding and acute hemodynamic collapse, especially if a larger volume of fluid is removed and increased blood pressure leads to further brisk bleeding into the pericardial space. Therefore in a relatively stable patient with acute type A dissection and cardiac tamponade, the risks associated with pericardiocentesis probably outweigh its benefits. In studies from Asia, however, pericardiocentesis for cardiac tamponade complicating IMH has been reported to be safe.¹⁴ Hypotension or shock from hemopericardium secondary to ascending dissection requires emergency aortic surgery. For patients who will not survive until surgery, pericardiocentesis with aspiration of only enough pericardial fluid to stabilize the patient before surgery may be lifesaving and should be considered a treatment option in this setting.^{14,57}

Definitive Therapy

Definitive therapy for acute aortic dissection includes emergency surgery for patients with acute ascending aortic dissection who are considered surgical candidates. Patients with acute type A aortic dissection have a risk for complications, including aortic rupture, aortic regurgitation with heart failure, stroke, cardiac tamponade, and visceral ischemia. When compared with medical therapy, immediate surgical treatment improves survival in patients with acute type A aortic dissection.^{14,39} In the IRAD, the mortality rate of patients with type A aortic dissection undergoing surgery was 26%, as opposed to 58% in those treated medically (typically because of advanced age and comorbid conditions) (**Fig. 57-18**).³⁹ The Society of Thoracic Surgery reported a 21.5% mortality rate in more than 9000 emergency type A aortic dissection repairs.²⁶ Thus many patients with acute ascending aortic dissection will die even after arriving at centers with extensive experience in treating aortic dissection.^{37,49,58} Other single-center series have reported even lower mortality for surgical patients.⁵⁹ Patients with acute ascending dissection undergoing surgery have variable mortality, depending on the risk factors present preoperatively.^{14,37,49} In the IRAD, patients considered unstable (shock, congestive heart failure, cardiac tamponade, MI, renal failure, or mesenteric ischemia) had a mortality rate of 31% as compared with 17% in patients without unstable features.³⁷ Patients with a preoperative malperfusion syndrome and type A dissection have several-fold higher mortality than do patients without malperfusion.^{14,49}

A bedside preoperative and postoperative risk prediction tool for mortality permits estimation of the risks associated with surgery for

FIGURE e57-15 Observed versus model probabilities of death by preoperative score. Example: A 77-year-old woman had migrating chest pain, preoperative cardiac tamponade, a pulse deficit, and ST elevation. Her model score is 0.7 (age >70) + 0.9 (migratory chest pain) + 1.0 (preoperative cardiac tamponade) + 0.6 (pulse deficit) + 0.6 (ST elevation). Total score = 3.8. Estimated surgical mortality risk = 61%. (From Rampoldi V, Trimarchi S, Eagle KA, et al: Simple risk models to predict surgical mortality in acute type A aortic dissection: The International Registry of Acute Aortic Dissection score. *Ann Thorac* 83:55, 2007.)

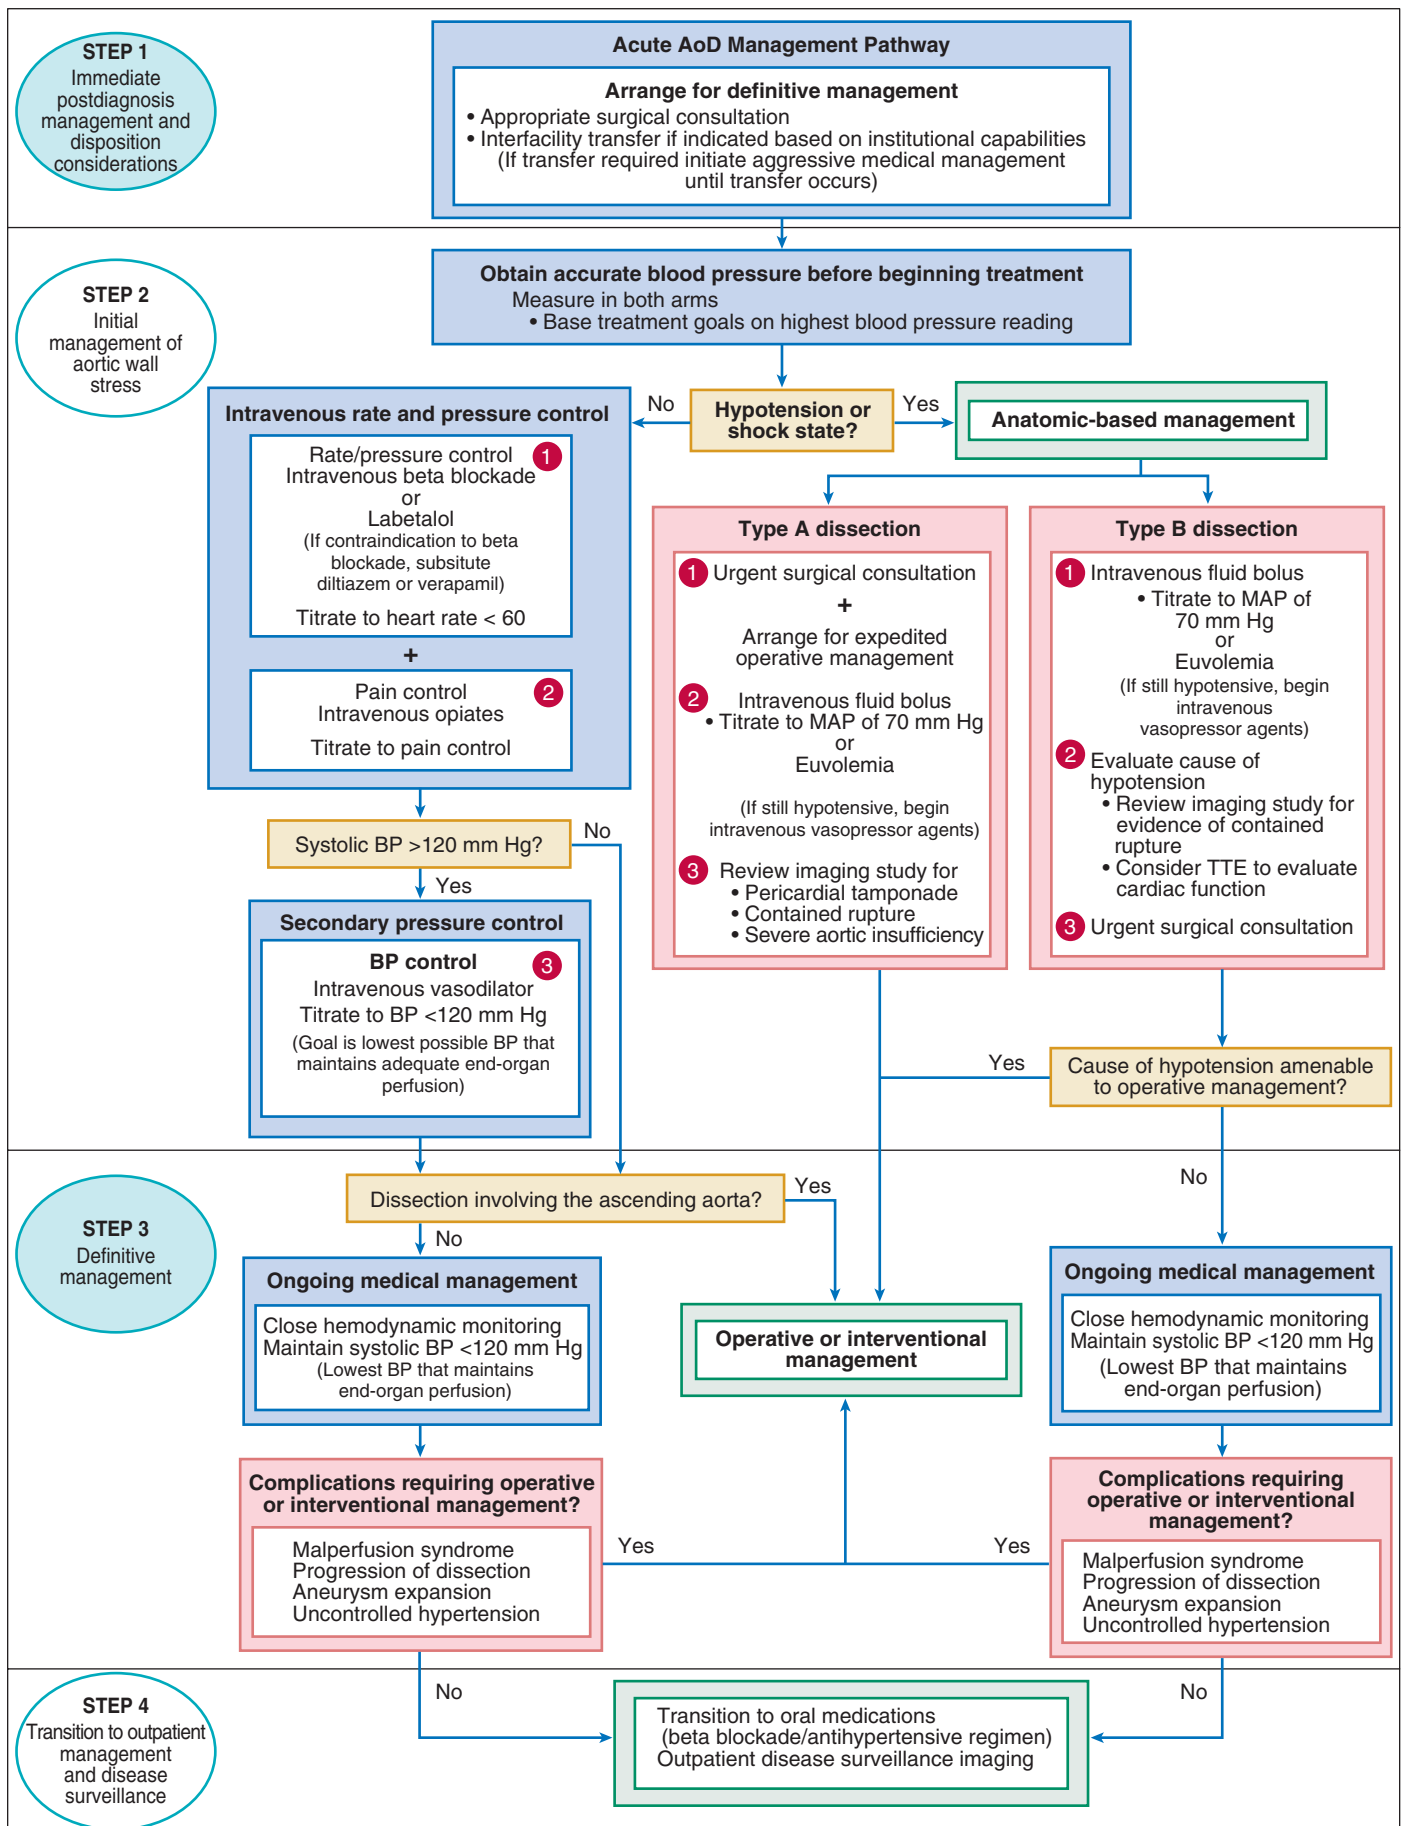

FIGURE 57-17 Management pathway for acute aortic dissection. AoD = aortic dissection; BP = blood pressure; MAP = mean arterial pressure. (From Hiratzka LF, Bakris GL, Beckman JA, et al: 2010 ACCF/AHA/AATS/ACR/ASA/SCA/SCAI/SIR/STS/SVM guidelines for the diagnosis and management of patients with thoracic aortic disease: Executive summary. A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, American Association for Thoracic Surgery, American College of Radiology, American Stroke Association, Society of Cardiovascular Anesthesiologists, Society for Cardiovascular Angiography and Interventions, Society of Interventional Radiology, Society of Thoracic Surgeons, and Society for Vascular Medicine. *Circulation* 121:e266, 2010.)

acute type A aortic dissection (Table e57-4, see also Fig. e57-15).⁶⁰ Intraoperative variables, including hypotension, right ventricular dysfunction, and surgical aspects (CABG, partial arch resection), are also used in obtaining a postoperative score. One may use these data to estimate an individual's expected mortality rate with acute type A aortic dissection. Even though prompt identification plus surgery is the best hope for survival, this risk score may be useful in the management of truly moribund patients whose chance of survival, regardless of surgery, is very poor.⁶⁰

Selected patients with type A dissection deemed to be poor operative candidates have undergone endovascular therapy, but understanding the role of TEVAR in this setting will require much more data (Fig. e57-16).⁶¹

Patients with acute type B aortic dissection have a lower acute mortality rate than do those with acute type A dissection. In the IRAD, the mortality rate of patients with type B dissection treated medically was 10.7% (see Fig. 57-17), but most series of acute type B aortic dissection have reported a mortality rate of between 25% and 50% in patients requiring OSR. In patients with uncomplicated type B dissection, the in-hospital mortality rate is much lower—as low as 1% to 6% in those requiring only medical therapy^{62,63}—but complicated type B dissection carries a much higher mortality rate, especially when accompanied by shock or malperfusion. In the IRAD, surgery was performed in 20% of patients with type B dissection, with a mortality rate of 31%.³⁹ In a series of 159 acute type B aortic dissections treated with initial medical therapy, the in-hospital mortality rate was 8.8%; when early vascular intervention was required, 17%; and when medical management was maintained, 7.4%. Uncomplicated acute type B dissection requiring only medical therapy had a very low mortality rate of 1.2% in this series.⁶³ Medical therapy provides an outcome superior to that of initial surgical therapy for uncomplicated type B aortic dissection. Typical indications for surgical—or more commonly, endovascular—intervention in patients with type B aortic dissection include complications such as visceral or limb ischemia, aortic rupture or impending rupture, rapid expansion of the aortic diameter, uncontrollable pain, or retrograde extension of the dissection into the ascending aorta (Table 57-7) (Fig. e57-17).

TABLE 57-7 Indications for Surgical, Endovascular, and Medical Therapy for Acute Aortic Dissection

Surgical Therapy
Acute type A aortic dissection
Retrograde dissection into the ascending aorta
Endovascular and/or Surgical Therapy
Acute type B aortic dissection complicated by
Visceral ischemia
Limb ischemia
Rupture or impending rupture
Aneurysmal dilation
Refractory pain
Medical Therapy
Uncomplicated type B aortic dissection
Uncomplicated isolated arch dissection

The preferred therapy for most complications currently includes endovascular therapy.^{14,30,64}

Primary arch dissections are uncommon, and management of this condition must be individualized. Surgical repair of acute arch dissection has a mortality between 15% and 29%. If the ascending aorta is involved, the dissection is classified as type A and emergency surgery is recommended. Many advocate initial medical therapy for primary arch dissections that do not involve the ascending aorta, whereas others recommend emergency surgery for some primary arch dissections, especially if aneurysmal enlargement is present. Type B dissections that extend retrogradely into the transverse arch have been managed variably. Initial medical therapy is recommended for most.

Isolated abdominal aortic dissections are rare and associated with hypertension and preexisting aneurysm disease.⁶⁵ Most are spontaneous dissections, although trauma and iatrogenic causes account for approximately 20%. Open surgery and endovascular techniques have been used in this condition.

FIGURE 57-18 Two-week mortality rates for acute aortic dissection according to dissection type and medical or surgical treatment. (From Hagan PG, Nienaber CA, Isselbacher EM, et al: *The International Registry of Acute Aortic Dissection (IRAD): New insights into an old disease.* JAMA 283:897, 2000.)

Surgical Management. Generally accepted indications for definitive surgical (or endovascular) therapy are summarized in Table 57-7. Operative therapy for acute aortic dissection is technically very demanding. The aortic wall is thin and friable, and Teflon felt and sutures with pledgets are used to buttress the wall and prevent the sutures from tearing the fragile aortic wall.

Type A Aortic Dissection. Open surgery, performed as expeditiously as possible, is the treatment of choice for ascending aortic dissection to prevent life-threatening complications.¹⁴ Surgery is performed to excise the proximal entry tear, prevent pericardial rupture, prevent or treat coronary ostial dissection, correct aortic valve regurgitation, restore flow into the true lumen, correct malperfusion, and if possible, obliterate the false channel distally.²⁸ Although some controversy exists regarding the timing of directly treating malperfusion, the general consensus when this complication accompanies acute type A dissection is to repair the aorta first because this will correct the malperfusion in most patients.¹⁴ The early mortality rate for surgical treatment of acute type A dissection has been reported to be approximately 20% to 25% in large series, whereas that for single-center experience is often lower.^{14,39,46,58,59} A median sternotomy is performed routinely, and cannulation for cardiopulmonary bypass generally involves the axillary artery (or less commonly, the femoral approach) to avoid trauma to the weakened aortic wall.⁴⁶ Technical considerations for the cannulation site and maintaining distal perfusion are critical.²⁸ A prosthetic interposition graft replaces the ascending aorta, and surgeon-specific methods to support the anastomosis are used.²⁸ Most patients can be treated by obliteration of the false lumen by placement of Teflon felt as a neomedia and resuspension of the native aortic valve.⁶⁶ Intraoperative aortic valve inspection and TEE guidance assist in managing the aortic valve in patients with proximal aortic

TABLE e57-4 Preoperative Prediction Model of Risk for Surgical Mortality

VARIABLE	OVERALL TYPE A (%)	% IN SURVIVORS	% IN THOSE WHO DIED	COEFFICIENT	SCORE ASSIGNED	P VALUE	ODDS RATIO FOR DEATH (95% CI)
Age ≥70 years	27.3	24.1	37.4	0.68	0.7	<0.01	1.98 (1.19-3.29)
History of aortic valve replacement	4.5	3.8	6.6	1.44	1.5	<0.01	4.21 (1.56-11.34)
Initially seen with hypotension, shock, or tamponade	28.8	22.4	49.0	1.17	1.2	<0.01	3.23 (1.95-5.37)

FIGURE e57-16 TEVAR of chronic ascending aortic dissection with treatment of the intimal tears in the ascending and descending aorta in one setting. **A**, CTA demonstrating an intimal tear in the ascending aorta and false lumen patency 36 days after acute type A dissection. **B**, Completion aortography after TEVAR demonstrating patency of the arch vessels. **C**, CTA at 24 months demonstrating complete thrombosis of the false lumen after TEVAR of the ascending aorta and descending aorta. (From Lu Q, Feng J, Zhou J, et al: Endovascular repair of ascending aortic dissection: A novel treatment option for patients judged unfit for direct surgical repair. *J Am Coll Cardiol* 61:1917, 2013.)

FIGURE e57-17 CT scan of an acute type B aortic dissection (white arrow) with contained rupture of the aorta (black arrow).

dissection.⁴⁶ When aortic regurgitation complicates dissection, repair of the aortic wall, decompression of the false lumen, and resuspension of the commissures to the aortic wall will usually restore valve competence. In approximately 20% to 25% of patients (notably those with a markedly dilated annulus and moderate to severe aortic regurgitation) who undergo conservative valve management, root dilation or progressive aortic regurgitation may develop late and require AVR or root replacement.⁴⁶ When aortic leaflet disease precludes repair, AVR plus associated ascending aortic replacement is indicated. When the sinuses are very dilated, composite valve and root replacement is often performed via the modified Bentall procedure. When the aortic root and sinuses are dilated but the aortic leaflets are normal, many have achieved success by performing a valve-sparing root replacement, typically using the reimplantation technique (see Fig. 57-7).^{14,27} This complex process requires a longer procedure and surgical expertise, however, and for many, composite valve and root replacement is more appropriate. In the German Registry for Acute Aortic Dissection Type A (GERAADA), more than 70% of patients received a supra-commissural ascending aortic graft, 20% underwent composite valve grafting, and less than 8% underwent aortic valve-sparing root replacement.^{46,58}

The aortic arch is dissected in more than 70% of type A dissections, and arch vessel involvement in the dissection process is reported in 28% to 73%.^{14,46,47} Arch replacement, with the patient under deep hypothermic circulatory arrest, is also performed if the aortic arch is aneurysmal or ruptured or has a primary arch tear at the time of surgical treatment and in some patients with genetically determined aneurysm syndromes. Although more complex procedures in which the entire aortic arch is replaced may reduce patency of the false lumen, this complex procedure carries more risk than does hemiarch²⁸ or ascending aortic surgery.^{30,67} The elephant trunk and the frozen elephant trunk procedures (see discussion in the section [Thoracic Aortic Aneurysms](#)) have been extended to some with acute type A dissection

requiring extensive repair, especially those with type A dissection and rupture of the descending aorta (Fig. 57-19).^{28,46}

Type B Aortic Dissection. Treatment of patients with type B aortic dissections is currently evolving with the increased use of endovascular devices. Because of the high mortality rates associated with surgery, stable patients with uncomplicated type B dissection usually receive nonoperative treatment.^{14,68} Patients with complicated type B aortic dissection secondary to aortic rupture (Fig. 57-20), intractable pain, and/or end-organ ischemia because of aortic branch vessel involvement require intervention, but OSR is associated with high mortality rates. Such patients have increasingly been undergoing endovascular treatment, with encouraging results.^{30,64} Rapid aortic expansion and aneurysmal enlargement greater than 5.5 cm are also indications for TEVAR.⁶⁴ Of 571 patients with type B dissection in the IRAD, 68% were treated medically. Of patients with complicated type B dissection, 10% underwent OSR and had a mortality rate of 33%, whereas 12% underwent TEVAR and had a mortality rate of 11%.⁶⁴

Aortic fenestration techniques with or without additional aortic branch stenting have produced reasonable success in the treatment of patients with aortic branch vessel involvement and malperfusion syndromes. When a dead-end false lumen leads to dynamic compression of the true lumen, balloon fenestration of the intimal flap allows blood to flow from the false into the true lumen, thereby decompressing the distended false lumen. Another technique involves percutaneous stenting of an affected arterial branch in which the dissection process has compromised flow.

Endovascular grafts can be used to treat most complications of type B dissections with relatively low morbidity and mortality rates in comparison to emergency open surgery (see Fig. 57-8). The rationale behind this technique is that covering the area of the primary intimal tear with the endovascular graft redirects flow to the true lumen and promotes thrombosis of the false lumen, thereby allowing aortic remodeling (Fig. 57-21). This treatment often corrects malperfusion

FIGURE 57-19 A, Supracommissural replacement of the ascending aorta. B, Hemiarch replacement. C, Total arch replacement. D, Trifurcated graft technique. E, Frozen elephant trunk procedure. (From Kruger T, Conzelmann LO, Bonser RS, et al: Acute aortic dissection type A. *Br J Surg* 99:1331, 2012.)

FIGURE 57-20 Rupture of type B aortic dissection. **A**, Contrast-enhanced CT demonstrating early leakage of blood from the dilated false lumen (arrows). The small true lumen is densely opacified with contrast material. **B**, Non-contrast-enhanced CT demonstrating acute hemorrhage from the ruptured type B dissection (arrows). Ao = aorta. **C**, Three-dimensional reconstruction of the descending thoracic aorta after emergency endovascular repair of the ruptured aortic dissection.

FIGURE 57-21 TEVAR after aortic dissection in the setting of aneurysmal enlargement of the false channel. **A**, An endograft is advanced to cover the proximal entry tear into the false channel. **B**, Sealing of the entry tear promotes thrombosis in the false lumen. **C**, Remodeling of the aorta occurs with expansion of the true lumen and a smaller, thrombosed false lumen.

syndromes and branch vessel ischemia (**Fig. 57-22**) and is useful in the treatment of enlarging symptomatic dissections (**Fig. 57-23**) and ruptured aortas. The STABLE (Study of Thoracic Aortic Type B Dissection Using Endoluminal Repair) trial and other studies are evaluating the treatment of acute complicated type B dissection with endovascular grafts. Up to two thirds of patients so treated have persistence of a perfused false lumen, which can require reintervention and surgical conversion. If malperfusion of a branch vessel persists, branch vessel stenting or the technique of provisional extension to induce complete attachment (PETTICOAT)—in which the entry point is sealed with an endograft and the remaining thoracic aorta and potentially the abdominal aorta are stented open—may address this problem.⁶⁴ This approach can decrease the chance of true lumen collapse, enhance aortic remodeling, and promote thrombosis of the false lumen. Innovative “hybrid” approaches to surgical and endovascular repair of dissections involving the arch and descending aorta are being performed with successful early results, but long-term data are lacking. Retrograde ascending aortic dissection is a potentially lethal complication that may occur during TEVAR for type B dissection, thus emphasizing the requirement for an open repair team at institutions performing endografts for aortic dissection.^{14,43}

Patients with uncomplicated type B aortic dissection are at risk for long-term complications, including aneurysm formation, late rupture, and dissection. Whether early endovascular grafting of uncomplicated type B dissection changes the natural history of this disease is under investigation. The INSTEAD (INvestigation of STent Grafts in Patients With Type B Aortic Dissection) trial randomly assigned 140 patients with stable, uncomplicated, chronic type B dissection to endovascular grafting versus medical therapy.⁶⁹ TEVAR had no advantage over medical therapy regarding survival, aortic rupture, or need for reintervention at the 2-year follow-up, but patients treated with TEVAR had a significantly higher rate of aortic remodeling, including false lumen thrombosis and true lumen expansion (91% versus 19% for TEVAR versus medical therapy)⁶⁹ (**Fig. 57-23**). More than 20% of patients randomly assigned to optimal medical therapy later underwent TEVAR because of aneurysmal enlargement of the aorta after dissection.⁵⁰ The ADSORB (A European Study on Medical Management Versus TAG Device + Medical Management for Acute Uncomplicated Type B Dissection) trial will enroll patients with acute uncomplicated type B dissection in Europe, will compare TEVAR with medical therapy, and will examine endpoints, including false lumen thrombosis, aortic dilation, rupture, and dissection-related and overall mortality after 1 year and 3 years.

Definitive Medical Management

As discussed earlier, many patients require multiple antihypertensive agents to control their blood pressure acutely, but blood pressure

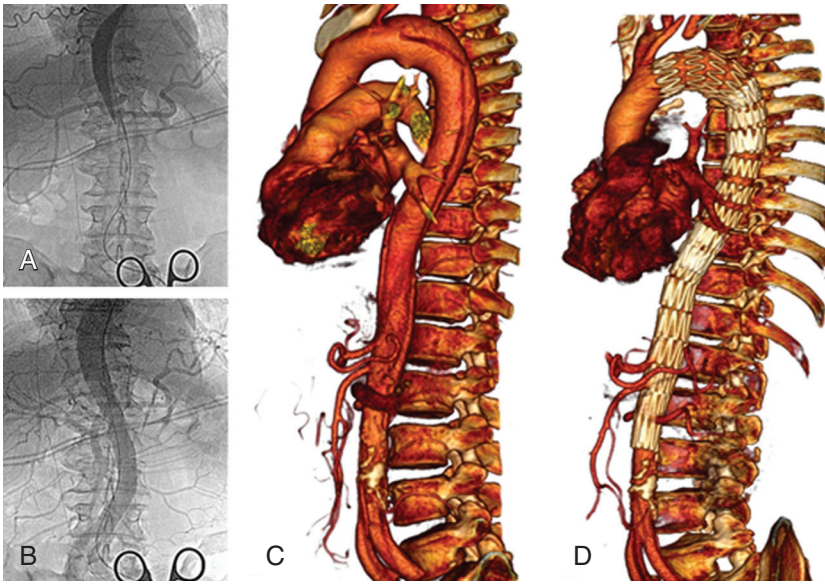

FIGURE 57-22 Complicated acute type B aortic dissection with aortic malperfusion above the renal arteries before and after emergency stent-graft implantation. **A**, Aortogram with no flow to the abdominal aorta. **B**, Aortogram demonstrating markedly improved distal flow after stent-graft placement. **C**, Three-dimensional reconstruction of the complicated type B dissection before TEVAR. **D**, After stent-graft placement. (From Akin I, Kische S, Tehders TC, et al: TEVAR, the solution to all aortic problems? *Herz* 36:539, 2011.)

often falls over the first several days as the inflammatory response resolves. Persistence of severe hypertension or signs of renal ischemia should prompt evaluation for renal artery involvement. The patient should be observed closely for malperfusion syndromes involving the viscera or extremities and for evidence of aortic rupture. Mesenteric ischemia may be difficult to identify, and recognition of this serious complication requires vigilance.⁷⁰

Long-Term Therapy and Follow-Up

Short- and long-term survival rates for type A aortic dissection have ranged between 52% and 94% at 1 year and between 45% and 88% at 5 years.^{14,36} Others have reported that patients with type A dissection who survive surgery have survival rates of approximately 90% at 1 year, 75% at 5 years, and 54% at 10 years.⁴⁶ The 10-year actuarial survival rate in patients with acute aortic dissection who survived the initial hospitalization in various studies has ranged between 30% and 60%. In a single-center study of long-term follow-up after type A aortic dissection, the 10-year survival rate was 55% and the 20-year survival rate was 30%.⁵⁹

Medically treated patients with type A aortic dissection have a very high mortality rate, with death rates in excess of 50% reported early after diagnosis. Little information exists in the literature about the natural history and management of chronic type A aortic dissection. Some studies report dismal survival with medical therapy alone, even in patients who survive the initial hospitalization, but survival and hospital discharge rates of 41% were reported in a group of medically managed patients with type A aortic dissection.²⁸ In one series, only two thirds of patients who survived hospitalization for acute type A aortic dissection with medical therapy alone were still alive at 3 years.⁷¹ A few patients are initially seen when in the subacute stage, and they should undergo surgery. On occasion, patients are incidentally discovered to have a chronic type A dissection in an evaluation for aortic regurgitation or a dilated ascending aorta. In general, most have advocated surgical treatment for all appropriate candidates with chronic type A dissection, but some have reserved surgery for those with aneurysmal dilation of the ascending aorta, aortic regurgitation, or relatively young age. The in-hospital mortality rate associated with surgical therapy for chronic type A aortic dissection ranges from 8% to 17%, depending on the series.

Long-term survival rates in patients with acute type B dissection range from 56% to 92% at 1 year and from 48% to 82% at 5 years.⁷² These studies have included single-center reports with heterogeneous enrollment criteria and lack of endovascular therapy. Nonetheless, findings at long-term follow-up after type B aortic dissection are worse than after type A dissection, with about one in four patients dying within 3 years.³⁷ Previous studies have demonstrated that many deaths in follow-up are related to subsequent aortic complications such as rupture, extension of the dissection, and the risks associated with subsequent aortic and vascular surgery. An IRAD study reported the 3-year survival rates of patients discharged after initial hospitalization for acute type B aortic dissection. Survival rates in patients treated medically, surgically, or with endovascular therapy were $78 \pm 7\%$, $83 \pm 19\%$, and $76 \pm 25\%$, respectively.³⁷

Tenets of long-term management after aortic dissection include medical therapy, as well as antihypertensive therapy; screening the patient and first-degree relatives for genetically triggered disorders associated with aortic dissection; serial imaging of the aorta over time; lifestyle modifications; and education.

One important long-term management goal after dissection is treating hypertension, with a blood pressure goal of lower than 120/80 mm Hg in most individuals. Previous studies have demonstrated an

increase in late morbidity and mortality in patients with dissection and poorly controlled hypertension.^{72,73} Beta blockers are the drugs of first choice because of their effect on aortic stress and dP/dt , and they are recommended even in the absence of hypertension.¹⁴ Angiotensin blockade may protect against late aortic complications. In a nonrandomized, observational report from the IRAD, calcium channel-blocking agents were associated with reduced morbidity in medically treated patients with dissection.⁷⁴ Whether these or alternative antihypertensive agents have a unique role in management after dissection is unknown. Smoking cessation and risk factor modification for atherosclerotic disease are also important in management.¹⁴

Although most patients who experience acute aortic dissection have underlying hypertension, only a small fraction of hypertensive patients ever suffer a dissection. Many patients with dissection will eventually be found to have an underlying genetic predisposition to aortic disease. Some have syndromic features recognized as MFS or LDS; features of these disorders should be sought on examination. Recognition of dural ectasia—widening or enlargement of the dural canal, usually in the lumbosacral spine—on CT or MRI often indicates an underlying genetic aneurysm syndrome (such as MFS or LDS) (Fig. 57-24). Some patients will have an underlying BAV, a familial condition in 9% of cases; other patients will have familial TAA or dissection syndromes. Comprehensive family studies have recognized that 20% of individuals with a TAA or dissection have another first-degree relative with thoracic aortic disease.¹⁴ Thus individuals with aortic dissection should undergo evaluation for a genetic disorder, and all first-degree relatives should be evaluated for TAA disease.¹⁴

Long-term management after dissection also includes regular imaging of the aorta and its branches for complications, especially aneurysmal enlargement (Fig. e57-18). The distal arch and the proximal descending aorta are the areas at highest risk for late aneurysm formation after acute type A aortic dissection.²⁸ In some series, between 2% and 13% of patients require reoperation within 5 years,²⁸ whereas others report a much higher rate. The risk associated with repeated surgery or intervention 10 years after type A aortic dissection ranges from 16% to 25%.⁴⁶ Reoperation may be necessary because of aneurysm formation at the site of dissection, recurrent dissection, rupture, aneurysm formation at a remote site, graft dehiscence or

FIGURE e57-18 Progressive aneurysmal enlargement of the descending aorta following type B aortic dissection. **A**, CT scan demonstrating acute type B aortic dissection (*arrow*). **B**, The false lumen (*arrow*) has dilated 1 year after the acute dissection. **C**, Further enlargement of the false lumen (*arrow*) with aneurysmal enlargement 3 years after the acute dissection.

FIGURE 57-23 **A**, Type B aortic dissection with partial thrombosis of the false lumen (arrow). **B**, After endovascular repair of the type B dissection, the false lumen has collapsed and remodeled and is no longer visualized (arrow). FL = false lumen; TL = true lumen.

pseudoaneurysm formation, aortic valve regurgitation, or infection. Typical protocols for follow-up after acute dissection include imaging with CT or MRA at 1 to 3, 6, 12, 18, and 24 months, with intervals depending on the size of the aorta and changes in aortic dimension over time. One advantage of MRA for long-term follow-up is avoidance of repeated radiation exposure. Reevaluation at least yearly thereafter is important to survey for aneurysmal dilation or expansion of the false lumen (Fig. e57-18).

Risk factors for late aneurysm formation include aortic dilation, hypertension, nonresection of the false lumen, larger false lumen diameter, and partial false lumen thrombosis.^{28,75} Patients with partial false lumen thrombosis (see Fig. 57-23) have higher mortality rates at follow-up than do those with a completely patent or completely thrombosed false lumen.³⁷ Increased pressure may occur in the false lumen in the setting of partial thrombosis because of the lack of distal reentry tears and lead to subsequent expansion and increased risk for rupture.³⁷ Additionally, false lumen thrombus may cause hypoxemia of the arterial wall and result in localized weakening of the wall. Ulcer-like projections (localized blood-filled pouches) protruding into the thrombosed false lumen on CT are associated with late aortic events.⁷⁵ Whether endovascular intervention used as primary therapy

FIGURE 57-24 Dural ectasia as a sign of underlying connective tissue disease in aortic dissection. A sagittal CT scan demonstrates acute aortic dissection (white arrows) and dural ectasia (black arrows) in the lumbosacral spine of a woman with previously undiagnosed MFS.

for certain patients with uncomplicated type B dissection will alter their natural history is unknown. To date, studies of subacute and chronic type B dissections have not shown mortality benefits from prophylactic endovascular stent placement.^{14,69}

Many late deaths following surgery for aortic dissection result from rupture of the aorta at the site of previous dissection or from rupture of another aneurysm at a remote site. Aneurysms related to expansion of the false lumen have relatively thin walls and are at higher risk for rupture than atheromatous aneurysms are. Thus continued surveillance of the entire aorta with surgical (or endovascular when appropriate) treatment of aneurysms at appropriate size thresholds is important for long-term survival. The timing of surgical repair for aneurysmal involvement of the residual aorta depends on several factors, including the patient's age and general medical condition, comorbid conditions, underlying disease process, rate of aneurysmal enlargement, and absolute size of the aorta. In general, when the diameter of the descending aorta after dissection exceeds 5.5 cm or the rate of aortic expansion exceeds 1 cm/year, surgical evaluation for repair is recommended.^{14,28} In patients at relatively lower surgical risk and in those with certain genetically triggered TAA diseases, repair at an aortic diameter of 5 to 5.5 cm may be appropriate.

Lifestyle modifications are necessary after aortic dissection. Isometric activities, including weightlifting, lead to increased blood pressure and aortic wall stress. Many individuals have to change jobs, modify their work activities, or be considered disabled as a result of aortic dissection and/or underlying aortic disease because of limitations placed on physical activity.

AORTIC DISSECTION VARIANTS

In addition to acute aortic dissection, aortic IMH and PAU are included in the acute aortic syndromes (see Fig. 57-9). These disorders may be identical to classic aortic dissection in their manifestations and cause acute chest or back pain, but they have important differences in their imaging and management. IMH is associated with many of the same risk factors as classic aortic dissection, whereas PAU is more common in the descending aorta and is associated with heavy calcification and atherosclerosis.

Aortic Intramural Hematoma

In approximately 5% to 10% of patients with acute aortic syndromes in Western series, a hematoma develops within the medial layer of the aortic wall with no evidence of an intimal flap or false lumen visualized on imaging or at surgery or autopsy.⁷⁶ These “noncommunicating” dissections are labeled as aortic IMH. IMH seems to result from primary rupture of the vasa vasorum and subsequent mural hemorrhage, although some debate this theory and state that nonvisualized, small intimal defects underlie IMH. In the IRAD, approximately 6% of aortic “dissections” were classified as IMH.⁷⁶ In Asian studies, approximately 25% of acute aortic syndromes qualify as IMH, thus suggesting a geographic difference in the incidence of IMH.^{77,78} When compared with classic aortic dissection, patients with IMH are older and more likely to have descending aortic involvement.⁷⁶

IMH is classified as type A or type B according to the same classification scheme as used for classic aortic dissection. The symptoms and risk factors associated with IMH are similar to those of aortic dissection, with acute chest and/or back pain predominating. The proximity of the IMH to the adventitia may explain the frequent coexistence of pleural and pericardial effusion and underlies the higher risk for subsequent aortic rupture associated with IMH. Ascending IMH may lead to aortic regurgitation, hemopericardium, or rupture.

Imaging studies useful for the diagnosis of IMH include TEE, CT, and MRI. TEE features of IMH include focal crescentic or circumferential aortic wall thickening, an eccentric aortic lumen, displaced intimal calcification, and areas of echolucency within the aortic wall (Fig. e57-19, Video 57-18). There is no evidence of an intimal flap, false lumen, or flow in the aortic wall. Aortic wall thickness in patients with IMH ranges from 5 to 25 mm. On non-contrast-enhanced CT, IMH appears as an area of high attenuation in the wall of the aorta (Fig. e57-20), whereas on contrast-enhanced CT, the aortic wall demonstrates low attenuation (because no contrast material enters the wall) (Fig. 57-25). MRI demonstrates focal thickening of the aortic wall, with phase-contrast cine and gradient echocardiography demonstrating no flow in the aortic wall (Fig. e57-21). High signal intensity on T2-weighted imaging may be visualized because of blood in the aortic wall with acute IMH, but signal intensity varies depending on the age of the hemorrhage. Aortography has low sensitivity for detecting IMH inasmuch as the disease involves the aortic wall and not the lumen.

Distinct from an aneurysm with mural thrombus, IMH has a smooth lumen and curvilinear wall (Fig. 57-25). In certain cases, differentiating IMH from aortic dissection with thrombosis of the false lumen, mural thrombus within an aortic aneurysm, or severe aortic atherosclerosis may be difficult. On TEE, identifying the intima—often calcified and echodense—helps in making this distinction. Thickening beneath the intima suggests IMH, whereas thickening above the

intima (on the luminal side) occurs with mural thrombus formation in an aneurysm. In contrast to aortic atherosclerosis, IMH is not typically associated with diffuse irregularities in the aortic intima surface unless related to a penetrating ulcer. The fate of IMH may vary, including progression to acute “classic” aortic dissection or aortic rupture, complete resolution of the hematoma with no evidence of the disorder on follow-up imaging, “persistence” without progression of the hematoma, and progressive aortic dilation and aneurysm formation.

Early studies from Western Europe and the United States reported that patients with type A IMH were at high risk for complications, including aortic dissection (25% to 50%), hemopericardium, and rupture, with mortality in excess of 30% with medical therapy alone.⁷⁶ In a review of 160 patients from 11 studies, mortality in patients with type A IMH treated medically was almost 50% and was 24% when treated surgically. Type B IMH is associated with lower mortality rates—10% to 13% with medical therapy and 15% with surgical repair.⁷⁸ Cardiac surgery for type B IMH is reserved for complications such as progression, impending rupture, or rupture. Descending IMH may progress to frank dissection and late aneurysm formation or may be reabsorbed completely (Fig. e57-22).

Reports from Japan and South Korea have suggested a much different approach to the management of type A IMH—namely, medical therapy, serial imaging, and careful observation with prolonged hospitalization as an initial strategy.⁷⁷ In a series of 101 patients with type A IMH from Korea, 16 underwent emergency surgery for hemodynamic instability and 85 were initially treated with medical therapy. Medically treated patients underwent weekly imaging studies, prolonged hospitalization, and delayed surgery (in 29% of patients) at a median of 27 days and had a mortality rate of 4%. Predictors of adverse outcomes in these patients included syncope, enlarged aortic diameter (>55 mm), and increased hematoma thickness (>16 mm).⁷⁷

With this approach, however, many patients with type A IMH have progressed to frank dissection, hemopericardium, or rupture requiring emergency surgery (Fig. e57-23). With the strategy of medical therapy for ascending IMH, 30% of patients initially treated medically and more than 50% of patients with IMH overall eventually undergo surgical repair.^{76,79} In the IRAD, of 64 patients with ascending IMH, 10 were treated medically, with a mortality rate of 40% secondary to rupture or dissection.⁷⁶ In a series of 36 patients with type A IMH, 7 underwent immediate surgery, 28 underwent initial medical therapy with subsequent conversion to surgical repair (33% of them progressed to acute dissection), and 1 patient was treated medically with resolution of the IMH.⁸⁰

Given the potential for unpredictable and catastrophic complications, most authorities continue to recommend immediate surgical therapy for type A IMH in patients at reasonable risk and medical management for patients with type B IMH.^{14,76} Management of localized arch IMH must be individualized, with some advocating initial medical therapy for this group.⁷⁸ Patients with type B IMH require continued surveillance after surgery and while receiving medical therapy. Complete resolution of type B IMH has been described in more than 50% in some series, whereas others have progressed to frank dissection, rupture, or late aneurysm formation. Predictors of resolution of type B IMH have included younger age, smaller aortic diameter (<4 to 4.5 cm), hematoma thickness less than 1 cm, and postoperative use of beta blockers.^{76,81}

Penetrating Atherosclerotic Aortic Ulcer

In PAU, an atherosclerotic lesion penetrates through the internal elastic lamina into the media, often associated with a variable degree of IMH formation.⁸² PAUs may lead to pseudoaneurysm formation, aortic rupture, or late aneurysm. Aortic ulcers may be single or multiple and range from 5 to 25 mm in diameter and 4 to 30 mm in depth. PAUs are more common in the thoracic and abdominal aorta than in the arch or ascending aorta.

PAUs occur in 2% to 7% of symptomatic patients with suspected acute aortic syndrome.^{81,83} Patients with PAUs are typically elderly

with multiple coronary risk factors and coexisting vascular disease. Many patients have concomitant aneurysmal dilation of the aorta elsewhere, especially in the abdominal aorta.⁸² Even though up to 25% of PAUs are found incidentally on imaging studies, typical symptoms of PAUs include acute chest or back pain, similar in description to that of classic aortic dissection. Although PAUs may lead to aortic dissection, most patients do not have aortic regurgitation, pulse deficits, or visceral ischemia.

Imaging techniques for PAUs include CT, MRI, TEE, and aortography. Findings on CT include focal aortic ulceration, associated IMH, and a calcified, displaced intima (Fig. 57-26). Typically, a crater-like outpouching with irregular edges occurs in the setting of heavy atherosclerosis (Fig. e57-24A). CT may also demonstrate pleural effusions, mediastinal hemorrhage, coexisting aneurysms, contained rupture, pseudoaneurysm, and frank rupture. Most patients have some degree of IMH formation. CTA has identified atherosclerotic plaque rupture at the distal aortic arch in some cases of IMH.⁸¹ When a PAU is associated with aortic dissection, the dissection often involves a short segment of aorta and has a thick intimal flap. MRI findings in patients with PAUs include localized areas of high signal intensity in the aorta wall consistent with IMH, focal intimal thickening, and ulcer-like projections. TEE demonstrates aortic atherosclerosis with focal ulceration of the intima, often with hematoma.

PAUs have an uncertain natural history, with variability in the literature depending on patient selection. A PAU may “stabilize” or lead to complications, including IMH, distal embolization, aortic rupture, pseudoaneurysm (contained rupture), aortic dissection, or development of a saccular or fusiform aneurysm. In one study the annual growth rate of PAUs was 0.31 cm/year. Some investigators report gradual aortic enlargement and a low incidence of acute or life-threatening complications, whereas others report a high incidence of acute complications.^{81,83} Patients with PAUs require individualized management. In general, patients with ascending PAUs undergo surgical resection. Stable patients with type B PAUs may be managed medically, with close follow-up and serial imaging.⁸³ Patients who have an asymptomatic PAU discovered incidentally should undergo serial imaging studies to document stability.⁸² Patients with refractory or recurrent pain have an increased risk for disease progression. Those with a rapid increase in aortic dimension are at risk for rupture and should undergo invasive treatment, typically with endovascular stent-grafts.^{14,81} The short segment involved and the high-risk patient

population make endovascular repair a preferred technique for many (Fig. e57-24B, C). Endoleaks frequently complicate endovascular repair of PAUs because of dense atherosclerosis, mural thrombus, and irregular aortic wall architecture.⁸² Indications for surgery or TEVAR may include the development of hemorrhage, periaortic hematoma, expanding pseudoaneurysm, saccular aneurysm formation, continued pain, or rupture.⁸⁴ Other predictors of disease progression include increasing aortic wall thickness, ulcer craters greater than 20 mm in diameter or 10 mm in depth, increasing aortic hematoma, and increasing pleural effusion. A more aggressive approach may be required for type B PAUs than for classic type B dissection given the increased risk for rupture.

AORTOARTERITIS SYNDROMES

Bacterial Infections of the Aorta

Infected aortic aneurysms are a rare but lethal condition and account for less than 1% of all aneurysms undergoing surgery.⁸⁵ Infection may result from contiguous spread from adjacent thoracic tissues, such as mediastinitis, abscess, infected lymph nodes, empyema, or paravertebral abscess. Other causes include septic emboli from endocarditis and hematogenous dissemination of bacteria in the setting of sepsis or intravenous drug abuse. Infection most often arises in a diseased aorta, whether aneurysmal, atherosclerotic, or traumatized as a result of previous aortic cannulation or suturing.¹⁴ Even though the disease may be insidious in onset, it may also have a fulminant course with frequent aneurysm rupture (>50%) and a high mortality rate (>25% to 50%). Treatment involves resection of the aneurysm, débridement of infected soft tissue, antibiotics, and arterial reconstruction. Most patients are treated by in situ aortic grafting, whereas others undergo extra-anatomic bypass. Endovascular repair is performed selectively in high-risk patients.⁸⁶

The classic triad of an infected aortic aneurysm includes fever; abdominal, back, or chest pain; and a pulsatile tender mass. Most patients, however, do not have these pathognomonic findings. Patients are febrile, have leukocytosis, and have a high erythrocyte sedimentation rate. Most have positive blood cultures, but in some the organism is established only at the time of operative repair by culture and Gram stain of the aortic wall. Patients tend to have comorbid conditions, including diabetes and chronic disease, underlying immunocompromised states, or chronic steroid therapy. Many have recently undergone gastrointestinal operations or invasive procedures. Infected aneurysms most commonly involve the infrarenal aorta, with the paravisceral and juxtarenal aorta being involved less commonly. Infected TAAs are rare, most commonly affect the descending aorta, and are usually accompanied by rupture or pseudoaneurysm.⁸⁵ Infections of prosthetic aortic grafts occur in 1% to 2% and are characterized by abdominal or back pain and fever, and aortic graft–enteric erosion and fistula are common complications.

The most common microorganisms associated with infected aortic aneurysms include *Staphylococcus aureus* and *Salmonella* species, but infections with gram-negative bacilli and fungi can occur. Even though *Salmonella* can infect an underlying atherosclerotic aortic aneurysm, this microbe may directly penetrate an intact intima of a normal aortic wall and lead to arteritis and aneurysm formation. Thus one should always suspect underlying aortic seeding when *Salmonella* bacteremia occurs.

CT, MRI, and aortography may be diagnostic in patients with infected aortic aneurysms, and saccular aneurysms are most common. Features on CT include disruption of calcification, irregular wall thickening, a periaortic mass, rim enhancement, and periaortic stranding. The presence of gas and vertebral body erosion is highly suggestive of infection. Aortocaval or aortoenteric fistulas may complicate infected aneurysms. Infected aneurysms may expand rapidly and have a propensity to rupture, hence the importance of diagnosis. Because most descending or abdominal aneurysms are atherosclerotic, lack of calcium in an involved aorta may suggest an infected aneurysm. MRI features of infected aneurysms include a soft tissue mass, stranding fluid retention, and rim enhancement. Nuclear

FIGURE e57-24 **A**, Contrast-enhanced CT scan demonstrating an acute PAU with a focal pseudoaneurysm (*arrow*) involving the proximal descending aorta. medicine studies with $^{111}\text{indium}$ -labeled white blood cell scans have also been used.

Untreated infected aortic aneurysms generally expand and eventually rupture, often with rapid progression. *Salmonella* and other gram-negative infections have a greater tendency for early rupture and death. Overall mortality from infected aortic aneurysms exceeds 50% with medical therapy alone. Treatment of infected AAAs involves excision or exclusion of the infected aortic tissue, in situ or extra-anatomic bypass of the aorta and branches, débridement of infected periaortic tissue, and prolonged antibiotic therapy. Many infected aneurysms are in locations not amenable to conventional extra-anatomic reconstruction. When infrarenal AAAs are associated with extensive aortic and periaortic purulence, extra-anatomic bypass is performed. In situ bypass is more commonly performed in the setting of suprarenal aneurysms or infrarenal aneurysms with minimal purulence. Recent surgical series have reported operative mortality of 12% to 21%.⁸⁵

In a series of 32 patients with infected aortic aneurysms, 25 underwent open repair, with a mortality rate of 12% (versus 57% with medical therapy alone).⁸⁵ Because many patients have a high risk for complications of surgery for infected aortic aneurysms, some advocate endovascular repair for selected patients who are not suitable for open repair, either as a bridge to open repair or as definitive therapy.⁸⁶ Survival rates were 80% at 30 days and 50% at 1 year after endovascular treatment of selected cases of infected aortic aneurysms.⁸⁶

Prosthetic stent-graft infections are uncommon, and their true incidence is unknown. Pseudoaneurysm and aneurysm expansion and rupture may occur. Treatment includes removal of the infected stent-graft. The traditional repair strategy has been axillofemoral bypass with total graft excision and oversewing of the aorta stump, but recently, antibiotic-soaked in situ grafting has been used more often.⁸⁷

PRIMARY TUMORS OF THE AORTA

Tumors that affect the thoracic aorta most commonly arise secondarily from direct invasion by adjacent cancer or metastases, especially from the lung and esophagus.^{14,88} Primary aortic tumors are very rare, often feature embolism or arterial obstruction, and are usually unsuspected until histologic analysis reveals malignancy. The average age at diagnosis is 60 years, with a male preponderance.⁸⁸ Risk factors for aortic tumors are unknown, although previous radiation therapy, prosthetic grafts, and atherosclerosis may contribute. These tumors are most commonly located in the descending thoracic and abdominal aorta. Initial symptoms include pain, embolism (to the brain, legs, or viscera), intermittent claudication, renovascular hypertension, visceral ischemia, or constitutional symptoms. Less commonly, these tumors may cause hemorrhagic complications or invade adjacent structures. Three categories of tumors have been described: intraluminal (polypoid), intimal, and adventitial (mural). Intraluminal and intimal tumors are the most common. These tumors spread along the inner wall of the aorta and may appear polypoid on imaging. They may be accompanied by acute arterial embolization, with the embolus being a mixture of tumor and thrombus, or may lead to arterial obstruction or involvement of visceral arteries. Widely metastatic emboli may occur. Adventitial (mural) tumors are rare and grow to involve periaortic tissue and adjacent organs.

Aortic tumors are of mesenchymal origin and include intimal sarcoma, malignant fibrous histiocytoma, angiosarcoma, leiomyosarcoma, and undifferentiated sarcoma. CT may detect intimal tumors (Fig. 57-27), but the findings may mimic those of protruding atheroma. MRI is considered the most reliable imaging modality for diagnosis and may differentiate between tumor and atheromatous material. Findings on aortography are nonspecific and imitate those

FIGURE 57-27 Intimal sarcoma of the descending thoracic aorta in a 70-year-old woman. Contrast-enhanced CT shows an irregular low-density mass (arrows) partially filling the aortic lumen in the axial (A) and sagittal (B) planes. Extensive atherosclerotic calcifications appear throughout the aortic wall. (From Restrepo CS, Betancourt SL, Martinez-Jimenez S, et al: Aortic tumors. *Semin Ultrasound CT MR* 33:265, 2012.)

of an aneurysm or mural thrombus. If no metastases are present, resection with prosthetic graft replacement is recommended. Because of difficulty in achieving wide margins, tumors may recur locally. Palliative treatment of obstructive tumors includes endarterectomy, endovascular grafts, and extra-anatomic bypass. Chemotherapy and radiation therapy have been used in some cases with limited success. The average survival is approximately 1 year, and adventitial (mural) tumors have a better prognosis than intimal tumors do. In surgically treated patients, 3- and 5-year survival rates have been reported to be 11% and 8%, respectively.⁸⁸ Benign myxomas and fibromyxomas are much less common than malignant aortic tumors.

FUTURE PERSPECTIVES

Tremendous progress has been made in furthering our understanding of the basic mechanisms, genetic underpinnings, and cell signaling pathways involved in aortic aneurysm disease. These novel mechanisms of disease identify potential pathways for pharmacologic intervention. Large international studies of drug therapy, currently under way, may lead to effective prevention of TAA disease in certain genetic syndromes. This progress may translate into applications for many other aneurysm syndromes and could change the natural history of the disease.

Publication of guidelines for thoracic aortic disease has furthered awareness of the evaluation and treatment of these disorders. Large registries—including the IRAD, GERAADA, and GenTAC (Genetically Triggered Thoracic Aortic Aneurysms and Cardiovascular Conditions)—provide important clinical and translational platforms for understanding the basic mechanisms, clinical features, and treatment outcomes in aortic disease.

Advances in imaging the aorta structurally and functionally with techniques to understand the biomechanical forces, four-dimensional flow characteristics, and biologic activity in the aortic wall hold promise in understanding and managing patients with aortic disease. Finally, advances in surgical, endovascular, and hybrid approaches to therapy have transformed the management of highly complex aortic disease and lowered the morbidity and mortality associated with elective and emergency aortic procedures.

GUIDELINES

Diseases of the Aorta*

Alan C. Braverman

EVALUATION AND MANAGEMENT OF ACUTE THORACIC AORTIC DISEASE

Initial Evaluation and Management Recommendations for Estimation of Pretest Risk for Thoracic Aortic Dissection Class I

1. Providers should routinely evaluate any patient with complaints that may represent acute thoracic aortic dissection to establish a pretest risk for disease that can then be used to guide diagnostic decisions. This process should include specific questions about the medical history, family history, and pain features, as well as a focused examination to identify findings that are associated with aortic dissection, including the following:
 - a. High-risk conditions and historical features (*level of evidence: B*):
 - Marfan syndrome, Loeys-Dietz syndrome, vascular Ehlers-Danlos syndrome, Turner syndrome, or other connective tissue disease
 - Patients with mutations in genes known to predispose to thoracic aortic aneurysms and dissection, such as *FBNI*, *TGFBR1*, *TGFBR2*, *ACTA2*, and *MYH11*
 - Family history of aortic dissection or thoracic aortic aneurysm
 - Known aortic valve disease
 - Recent aortic manipulation (surgical or catheter based)
 - Known thoracic aortic aneurysm
 - b. High-risk chest, back, or abdominal pain features (*level of evidence: B*):
 - Pain that is abrupt or instantaneous in onset
 - Pain that is severe in intensity
 - Pain that has a ripping, tearing, stabbing, or sharp quality
 - c. High-risk examination features (*level of evidence: B*):
 - Pulse deficit
 - Systolic blood pressure limb differential greater than 20 mm Hg
 - Focal neurologic deficit
 - Murmur of aortic regurgitation (new)
2. Patients with sudden onset of severe chest, back, and/or abdominal pain, particularly those younger than 40 years, should be questioned about a history and examined for physical features of Marfan syndrome, Loeys-Dietz syndrome, vascular Ehlers-Danlos syndrome, Turner syndrome, or other connective tissue disorder associated with thoracic aortic disease. (*Level of evidence: B*)

Aortic Infections and Tumors

85. Hsu RB, Lin FY: Infected aneurysm of the thoracic aorta. *J Vasc Surg* 47:270, 2008.
86. Sedivy P, Spacek M, El Samman K, et al: Endovascular treatment of infected aortic aneurysms. *Eur J Vasc Endovasc Surg* 44:385, 2012.
87. Laser A, Baker N, Rectenwald J, et al: Graft infection after endovascular abdominal aortic aneurysm repair. *J Vasc Surg* 54:58, 2011.
88. Restrepo CS, Betancourt SL, Martinez-Jimenez S, et al: Aortic tumors. *Semin Ultrasound CT MR* 33:265, 2012.

3. Patients with a sudden onset of severe chest, back, and/or abdominal pain should be questioned about a history of aortic pathology in immediate family members because acute thoracic aortic disease has a strong familial component. (*Level of evidence: B*)
4. Patients with a sudden onset of severe chest, back, and/or abdominal pain should be questioned about recent aortic manipulation (surgical or catheter based) or a known history of aortic valvular disease because these factors predispose to acute aortic dissection. (*Level of evidence: C*)
5. In patients with suspected or confirmed aortic dissection who have experienced a syncopal episode, a focused examination should be performed to identify associated neurologic injury or the presence of pericardial tamponade. (*Level of evidence: C*)
6. All patients with acute neurologic complaints should be questioned about the presence of chest, back, and/or abdominal pain and be checked for peripheral pulse deficits because patients with dissection-related neurologic pathology are less likely than the typical aortic dissection patient to report thoracic pain. (*Level of evidence: C*)

Recommendations for Screening Tests Class I

1. An electrocardiogram should be obtained in all patients with symptoms that may represent acute thoracic aortic dissection.
 - a. Given the relative infrequency of dissection-related coronary artery occlusion, the presence of ST-segment elevation suggestive of myocardial infarction should be treated as a primary cardiac event without delay for definitive aortic imaging unless the patient is at high risk for aortic dissection. (*Level of evidence: B*)
2. The role of chest radiography in the evaluation of possible thoracic aortic disease should be directed by the patient's pretest risk for disease as follows:
 - a. Intermediate risk: A chest radiograph should be obtained for all intermediate-risk patients because it may establish a clear alternative diagnosis that will obviate the need for definitive aortic imaging. (*Level of evidence: C*)
 - b. Low risk: A chest radiograph should be obtained for all low-risk patients because it may either establish an alternative diagnosis or demonstrate findings suggestive of thoracic aortic disease and thus indicate the need for urgent definitive aortic imaging. (*Level of evidence: C*)
3. Urgent and definitive imaging of the aorta with transesophageal echocardiography, computed tomography, or magnetic resonance imaging is recommended to identify or exclude thoracic aortic dissection in patients determined to be at high risk for the disease by initial screening. (*Level of evidence: B*)

Class III

1. A negative finding on chest radiography should not delay definitive aortic imaging in patients determined to be high risk for aortic dissection by initial screening. (*Level of evidence: C*)

Recommendations for Diagnostic Imaging Studies

Class I

1. Selection of a specific imaging modality to identify or exclude aortic dissection should be based on patient variables and institutional capabilities, including immediate availability. (*Level of evidence: C*)

*Abstracted from Hiratzka LF, Bakris GL, Beckman JA, et al: 2010 ACCF/AHA/AATS/ACR/ASA/SCA/SCAI/SIR/STS/SVM guidelines for the diagnosis and management of patients with thoracic aortic disease. Executive summary: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, American Association for Thoracic Surgery, American College of Radiology, American Stroke Association, Society of Cardiovascular Anesthesiologists, Society for Cardiovascular Angiography and Interventions, Society of Interventional Radiology, Society of Thoracic Surgeons, and Society for Vascular Medicine. *Circulation* 121:1544, 2010.

2. If high clinical suspicion exists for acute aortic dissection but the findings on initial aortic imaging are negative, a second imaging study should be obtained. (*Level of evidence: C*)

Recommendations for Initial Management

Class I

1. Initial management of thoracic aortic dissection should be directed at decreasing aortic wall stress by controlling the heart rate and blood pressure as follows:
 - a. In the absence of contraindications, intravenous beta blockade should be initiated and titrated to a target heart rate of 60 beats/min or less. (*Level of evidence: C*)
 - b. In patients with clear contraindications to beta blockade, nondihydropyridine calcium channel-blocking agents should be used as an alternative for rate control. (*Level of evidence: C*)
 - c. If systolic blood pressure remains greater than 120 mm Hg after adequate control of the heart rate has been achieved, angiotensin-converting enzyme inhibitors and/or other vasodilators should be administered intravenously to further reduce blood pressure to levels that maintain adequate end-organ perfusion. (*Level of evidence: C*)
 - d. Beta-blocking agents should be used cautiously in the setting of acute aortic regurgitation because they will block the compensatory tachycardia. (*Level of evidence: C*)

Class III

1. Vasodilator therapy should not be initiated before rate control to avoid the associated reflex tachycardia, which may increase aortic wall stress and lead to propagation or expansion of a thoracic aortic dissection. (*Level of evidence: C*)

Recommendations for Definitive Management

Class I

1. Urgent surgical consultation should be obtained for all patients in whom thoracic aortic dissection is diagnosed regardless of the anatomic location (ascending versus descending) as soon as the diagnosis is made or highly suspected. (*Level of evidence: C*)
2. Acute thoracic aortic dissection involving the ascending aorta should be urgently evaluated for emergency surgical repair because of the high risk for associated life-threatening complications such as rupture. (*Level of evidence: B*)
3. Acute thoracic aortic dissection involving the descending aorta should be managed medically unless life-threatening complications develop (i.e., malperfusion syndrome, progression of dissection, enlarging aneurysm, inability to control blood pressure). (*Level of evidence: B*)

Recommendation for Surgical Intervention for Acute Thoracic Aortic Dissection

Class I

1. For patients with ascending thoracic aortic dissection, all of the aneurysmal aorta and the proximal extent of the dissection should be resected. A partially dissected aortic root may be repaired by aortic valve resuspension. Extensive dissection of the aortic root should be treated by aortic root replacement with a composite graft or with a valve-sparing root replacement. If a DeBakey type II dissection is present, the entire dissected aorta should be replaced. (*Level of evidence: C*)

Recommendation for Intramural Hematoma Without Intimal Defect

Class IIa

1. It is reasonable to treat intramural hematoma similar to aortic dissection in the corresponding segment of the aorta. (*Level of evidence: C*)

GENERAL APPROACH TO THE PATIENT

Recommendation for the History and Physical Examination for Thoracic Aortic Disease

Class I

1. For patients with a history of acute cardiac and noncardiac symptoms associated with a significant likelihood of thoracic aortic disease, the clinician should perform a focused physical examination, including a careful and complete search for arterial perfusion differentials in both the upper and lower extremities, evidence of visceral ischemia, focal neurologic deficits, a murmur of aortic regurgitation, bruits, and findings compatible with possible cardiac tamponade. (*Level of evidence: C*)

MANAGEMENT OF PATIENTS WITH THORACIC AORTIC DISEASE

Recommendation for Medical Treatment of Patients with Thoracic Aortic Diseases

Class I

1. Stringent control of hypertension, optimization of the lipid profile, smoking cessation, and other atherosclerosis risk reduction measures should be instituted for patients with small aneurysms not requiring surgery, as well as for patients not considered to be surgical or stent-graft candidates. (*Level of evidence: C*)

Recommendations for Blood Pressure Control

Class I

1. Antihypertensive therapy should be administered to hypertensive patients with thoracic aortic diseases to achieve a goal of less than 140/90 mm Hg (patients without diabetes) or less than 130/80 mm Hg (patients with diabetes or chronic renal disease) to reduce the risk for stroke, myocardial infarction, heart failure, and cardiovascular death. (*Level of evidence: B*)
2. Beta adrenergic-blocking drugs should be administered to all patients with Marfan syndrome and aortic aneurysm to reduce the rate of aortic dilation unless contraindicated. (*Level of evidence: B*)

Class IIa

1. In patients with a thoracic aortic aneurysm it is reasonable to reduce blood pressure with beta-blocking agents and angiotensin-converting enzyme inhibitors or angiotensin receptor-blocking agents to the lowest point that patients can tolerate without adverse effects. (*Level of evidence: B*)
2. An angiotensin receptor-blocking agent (losartan) is reasonable for patients with Marfan syndrome to reduce the rate of aortic dilation unless contraindicated. (*Level of evidence: B*)

Recommendation for Dyslipidemia

Class IIa

1. Treatment with a statin to achieve a target low-density lipoprotein cholesterol level of less than 70 mg/dL is reasonable for patients who have a coronary heart disease risk equivalent, such as noncoronary atherosclerotic disease, atherosclerotic aortic aneurysm, and coexistent coronary heart disease, and are at high risk for coronary ischemic events. (*Level of evidence: A*)

Recommendation for Smoking Cessation

Class I

1. Smoking cessation and avoidance of exposure to environmental tobacco smoke at work and at home are recommended. Follow-up,

referral to special programs, and/or pharmacotherapy (including nicotine replacement, bupropion, or varenicline) are useful, as is adopting a stepwise strategy aimed at smoking cessation (the five A's are Ask, Advise, Assess, Assist, and Arrange). (*Level of evidence: B*)

SURGICAL AND ENDOVASCULAR TREATMENT BY LOCATION OF DISEASE

Ascending Aorta and Aortic Sinuses Recommendations for Asymptomatic Patients with Ascending Aortic Aneurysms

Class I

1. Asymptomatic patients with a degenerative thoracic aneurysm, chronic aortic dissection, intramural hematoma, penetrating atherosclerotic ulcer, mycotic aneurysm, or pseudoaneurysm who are otherwise suitable candidates and in whom the diameter of the ascending aorta or aortic sinus is 5.5 cm or greater should be evaluated for surgical repair. (*Level of evidence: C*)
2. Patients with Marfan syndrome or other genetically mediated disorders (vascular Ehlers-Danlos syndrome, Turner syndrome, bicuspid aortic valve, or familial thoracic aortic aneurysm and dissection) should undergo elective surgery at smaller diameters (4.0 to 5.0 cm depending on the condition) to avoid acute dissection or rupture. (*Level of evidence: C*)
3. Patients with a growth rate greater than 0.5 cm/year in an aorta that is smaller than 5.5 cm in diameter should be considered for surgery. (*Level of evidence: C*)
4. Patients undergoing aortic valve repair or replacement and who have an ascending aorta or aortic root larger than 4.5 cm should be considered for concomitant repair of the aortic root or replacement of the ascending aorta. (*Level of evidence: C*)

Class IIa

1. Elective aortic replacement is reasonable for patients with Marfan syndrome, other genetic diseases, or bicuspid aortic valves when the ratio of maximal ascending or aortic root area in square centimeters divided by the patient's height in meters exceeds 10. (*Level of evidence: C*)
2. It is reasonable for patients with Loeys-Dietz syndrome or a confirmed *TGFBR1* or *TGFBR2* mutation to undergo aortic repair when the aortic diameter reaches 4.2 cm or greater by transesophageal echocardiography (internal diameter) or 4.4 to 4.6 cm or greater by computed tomography and/or magnetic resonance imaging (external diameter). (*Level of evidence: C*)

Recommendation for Symptomatic Patients with Thoracic Aortic Aneurysms

Class I

1. Patients with symptoms suggestive of expansion of a thoracic aneurysm should be evaluated for prompt surgical intervention unless life expectancy is limited because of comorbid conditions or quality of life is substantially impaired. (*Level of evidence: C*)

Recommendations for Open Surgery for Ascending Aortic Aneurysms

Class I

1. Separate valve and ascending aortic replacement is recommended in patients without significant aortic root dilation, in elderly patients, and in young patients with minimal dilation who have aortic valve disease. (*Level of evidence: C*)
2. Patients with Marfan, Loeys-Dietz, and Ehlers-Danlos syndromes and other patients with dilation of the aortic root and sinuses of Valsalva should undergo excision of the sinuses in combination with a modified David reimplantation operation if technically feasible or, if not, should undergo root replacement with a valved graft conduit. (*Level of evidence: B*)

Recommendations for Aortic Arch Aneurysms

Class IIa

1. For thoracic aortic aneurysms also involving the proximal aortic arch, partial arch replacement together with ascending aorta repair using right subclavian/axillary artery inflow and hypothermic circulatory arrest is reasonable. (*Level of evidence: B*)
2. Replacement of the entire aortic arch is reasonable for acute dissection when the arch is aneurysmal or extensive aortic arch destruction and leakage are present. (*Level of evidence: B*)
3. Replacement of the entire aortic arch is reasonable for aneurysms of the entire arch, for chronic dissection when the arch is enlarged, and for distal arch aneurysms that also involve the proximal descending thoracic aorta, usually with the elephant trunk procedure. (*Level of evidence: B*)
4. For patients with low operative risk in whom an isolated degenerative or atherosclerotic aneurysm of the aortic arch is present, operative treatment is reasonable for asymptomatic patients when the diameter of the arch exceeds 5.5 cm. (*Level of evidence: B*)
5. For patients with isolated aortic arch aneurysms less than 4.0 cm in diameter it is reasonable to reimagine with computed tomography or magnetic resonance imaging at 12-month intervals to detect enlargement of the aneurysm. (*Level of evidence: C*)
6. For patients with isolated aortic arch aneurysms 4.0 cm or greater in diameter it is reasonable to reimagine with computed tomography or magnetic resonance imaging at 6-month intervals to detect enlargement of the aneurysm. (*Level of evidence: C*)

Descending Thoracic Aorta and Thoracoabdominal Aorta

Recommendations for Descending Thoracic Aorta and Thoracoabdominal Aortic Aneurysms

Class I

1. For patients with chronic dissection, particularly if associated with a connective tissue disorder, no significant comorbid disease, and a descending thoracic aortic diameter exceeding 5.5 cm, open repair is recommended. (*Level of evidence: B*)
2. For patients with degenerative or traumatic aneurysms of the descending thoracic aorta exceeding 5.5 cm, saccular aneurysms, or postoperative pseudoaneurysms, endovascular stent-grafting should be strongly considered when feasible. (*Level of evidence: B*)
3. For patients with thoracoabdominal aneurysms in whom endovascular stent-graft options are limited and surgical morbidity is elevated, elective surgery is recommended if the aortic diameter exceeds 6.0 cm—or less if a connective tissue disorder such as Marfan or Loeys-Dietz syndrome is present. (*Level of evidence: C*)
4. For patients with thoracoabdominal aneurysms and end-organ ischemia or significant stenosis from atherosclerotic visceral artery disease, an additional revascularization procedure is recommended. (*Level of evidence: B*)

COUNSELING AND MANAGEMENT OF CHRONIC AORTIC DISEASES IN PREGNANCY

Recommendations for Counseling and Management of Chronic Aortic Diseases in Pregnancy

Class I

1. Women with Marfan syndrome and aortic dilation, as well as patients without Marfan syndrome who have known aortic disease, should be counseled about their risk for aortic dissection, in addition to the heritable nature of the disease, before pregnancy. (*Level of evidence: C*)
2. For pregnant women with known thoracic aortic dilation or a familial or genetic predisposition to aortic dissection, strict blood pressure control, specifically to prevent stage II hypertension, is recommended. (*Level of evidence: C*)

- For all pregnant women with known aortic root or ascending aortic dilation, monthly or bimonthly echocardiographic measurement of ascending aortic dimensions until birth is recommended to detect aortic expansion. (*Level of evidence: C*)
- For imaging of pregnant women with aortic arch, descending, or abdominal aortic dilation, magnetic resonance imaging (without gadolinium) is recommended instead of computed tomography to avoid exposing both the mother and fetus to ionizing radiation. Transesophageal echocardiography is an option for imaging the thoracic aorta. (*Level of evidence: C*)
- Pregnant women with aortic aneurysms should undergo delivery at locations where cardiothoracic surgery is available. (*Level of evidence: C*)

Class IIa

- Fetal delivery via cesarean section is reasonable for patients with significant aortic enlargement, dissection, or severe aortic valve regurgitation. (*Level of evidence: C*)

Class IIb

- If progressive aortic dilation and/or advancing aortic valve regurgitation is documented, prophylactic surgery may be considered. (*Level of evidence: C*)

PERIOPERATIVE CARE FOR OPEN SURGICAL AND ENDOVASCULAR THORACIC AORTIC REPAIRS

Recommendations for Preoperative Evaluation

Class I

- In preparation for surgery, imaging studies adequate to establish the extent of disease and the potential limits of the planned procedure are recommended. (*Level of evidence: C*)
- Patients with thoracic aortic disease requiring a surgical or catheter-based intervention who have symptoms or other findings of myocardial ischemia should undergo additional studies to determine the presence of significant coronary artery disease. (*Level of evidence: C*)
- Patients with unstable coronary syndromes and significant coronary artery disease should undergo revascularization prior to or at the time of thoracic aortic surgery or endovascular intervention with percutaneous coronary intervention or concomitant coronary artery bypass graft surgery. (*Level of evidence: C*)

Class IIa

- Additional testing is reasonable to quantitate the patient's comorbid status and develop a risk profile. Such testing may include pulmonary function tests, cardiac catheterization, aortography, 24-hour Holter monitoring, noninvasive carotid artery screening, brain imaging, echocardiography, and neurocognitive testing. (*Level of evidence: C*)
- For patients who are to undergo surgery for ascending or arch aortic disease and who have clinically stable, but significant (flow limiting) coronary artery disease, it is reasonable to perform concomitant coronary artery bypass graft surgery. (*Level of evidence: C*)

Class IIb

- For patients who are to undergo surgery or endovascular intervention for descending thoracic aortic disease and who have clinically stable, but significant (flow limiting) coronary artery disease, the benefits of coronary revascularization are not well established. (*Level of evidence: B*)

Recommendations for Surveillance of Thoracic Aortic Disease or Previously Repaired Patients

Class IIa

- Computed tomography or magnetic resonance imaging of the thoracic aorta is reasonable after a type A or B aortic dissection or

after prophylactic repair of the aortic root/ascending aorta. (*Level of evidence: C*)

- Computed tomography or magnetic resonance imaging of the aorta is reasonable at 1, 3, 6, and 12 months after dissection and, if stable, annually thereafter so that any threatening enlargement can be detected in timely fashion. (*Level of evidence: C*)
- When monitoring patients with imaging, use of the same modality at the same institution is reasonable so that similar images of matching anatomic segments can be compared side by side. (*Level of evidence: C*)
- If a thoracic aortic aneurysm is only moderate in size and remains relatively stable over time, magnetic resonance imaging instead of computed tomography is reasonable to minimize the patient's radiation exposure. (*Level of evidence: C*)
- Surveillance imaging similar to that for classic aortic dissection is reasonable in patients with intramural hematoma. (*Level of evidence: C*)

Recommendation for Employment and Lifestyle in Patients with Thoracic Aortic Disease

Class IIa

- For patients with a current thoracic aortic aneurysm or dissection or previously repaired aortic dissection, employment and lifestyle restrictions are reasonable, including avoidance of strenuous lifting, pushing, or straining that would require a Valsalva maneuver. (*Level of evidence: C*)

INSTITUTIONAL/HOSPITAL QUALITY CONCERNS

Recommendations for Quality Assessment and Improvement for Thoracic Aortic Disease

Class I

- Hospitals that provide regional care for patients with acute sequelae of thoracic aortic disease (e.g., procedures for thoracic aortic dissection and rupture) should participate in standardized quality assessment and improvement activities, including thoracic aortic disease registries. Such activities should include periodic measurement and regional/national interfacility comparisons of thoracic aortic disease–related procedural volumes, complications, and risk-adjusted mortality rates. (*Level of evidence: C*)
- Hospitals that provide regional care for patients with acute sequelae of thoracic aortic disease (e.g., procedures for thoracic aortic dissection and rupture) should facilitate and coordinate standardized quality assessment and improvement activities with transferring facilities and emergency medical service teams. Such activities might include the following:
 - Cooperative joint facility meetings to discuss opportunities for quality improvement
 - Interfacility and emergency medical service team comparisons of pretransfer care based on available outcome data and future performance measures developed in accordance with this guideline (*Level of evidence: C*)

DIAGNOSIS AND MANAGEMENT OF PATIENTS WITH THORACIC AORTIC DISEASE

Genetic Syndromes Associated with Thoracic Aortic Aneurysms and Dissection Recommendations for Genetic Syndromes

Class I

- An echocardiogram is recommended at the time of diagnosis of Marfan syndrome to determine aortic root and ascending aortic

- diameters and 6 months thereafter to determine the rate of enlargement of the aorta. (*Level of evidence: C*)
- Annual imaging is recommended for patients with Marfan syndrome if stability of the aortic diameter is documented. If the maximal aortic diameter is 4.5 cm or greater or if the aortic diameter shows significant growth from baseline, more frequent imaging should be considered. (*Level of evidence: C*)
 - Patients with Loeys-Dietz syndrome or a confirmed genetic mutation known to predispose to aortic aneurysms and aortic dissections (*TGFBR1*, *TGFBR2*, *FBN1*, *ACTA2*, or *MYH11*) should undergo complete aortic imaging at initial diagnosis and 6 months thereafter to establish whether enlargement is occurring. (*Level of evidence: C*)
 - Patients with Loeys-Dietz syndrome should undergo yearly magnetic resonance imaging from the cerebrovascular circulation to the pelvis. (*Level of evidence: B*)
 - Patients with Turner syndrome should undergo imaging of the heart and aorta for evidence of a bicuspid aortic valve, coarctation of the aorta, or dilation of the ascending thoracic aorta. If the findings on initial imaging are normal and no risk factors for aortic dissection are present, imaging should be repeated every 5 to 10 years or if otherwise clinically indicated. If abnormalities exist, annual imaging or follow-up imaging should be done. (*Level of evidence: C*)

Class IIa

- It is reasonable to consider surgical repair of the aorta in all adult patients with Loeys-Dietz syndrome or a confirmed *TGFBR1* or *TGFBR2* mutation and an aortic diameter of 4.2 cm or greater by transesophageal echocardiography (internal diameter) or 4.4 to 4.6 cm or greater by computed tomography and/or magnetic resonance imaging (external diameter). (*Level of evidence: C*)
- For women with Marfan syndrome contemplating pregnancy, it is reasonable to prophylactically replace the aortic root and ascending aorta if the diameter exceeds 4.0 cm. (*Level of evidence: C*)
- If the maximal cross-sectional area of the ascending aorta or root in square centimeters divided by the patient's height in meters exceeds a ratio of 10, surgical repair is reasonable because shorter patients have dissection at a smaller size and 15% of patients with Marfan syndrome have dissection at a size smaller than 5.0 cm. (*Level of evidence: C*)

Class IIb

- In patients with Turner syndrome and additional risk factors, including a bicuspid aortic valve, coarctation of the aorta, and/or hypertension, and in patients who attempt to become pregnant or

who become pregnant, it may be reasonable to perform imaging of the heart and aorta to help determine the risk for aortic dissection. (*Level of evidence: C*)

Recommendations for Familial Thoracic Aortic Aneurysms and Dissections

Class I

- Aortic imaging is recommended for first-degree relatives of patients with thoracic aortic aneurysm and/or dissection to identify those with asymptomatic disease. (*Level of evidence: B*)
- If the mutant gene (*FBN1*, *TGFBR1*, *TGFBR2*, *COL3A1*, *ACTA2*, *MYH11*) associated with aortic aneurysm and/or dissection is identified in a patient, first-degree relatives should undergo counseling and testing. Then only relatives with the genetic mutation should undergo aortic imaging. (*Level of evidence: C*)

Class IIa

- If one or more first-degree relatives of a patient with known thoracic aortic aneurysm and/or dissection are found to have thoracic aortic dilation, aneurysm, or dissection, imaging of second-degree relatives is reasonable. (*Level of evidence: B*)
- Sequencing of the *ACTA2* gene is reasonable in patients with a family history of thoracic aortic aneurysms and/or dissection to determine whether *ACTA2* mutations are responsible for the inherited predisposition. (*Level of evidence: B*)

Class IIb

- Sequencing of other genes known to cause familial thoracic aortic aneurysms and/or dissection (*TGFBR1*, *TGFBR2*, *MYH11*) may be considered in patients with a family history and clinical features associated with mutations in these genes. (*Level of evidence: B*)
- If one or more first-degree relatives of a patient with known thoracic aortic aneurysm and/or dissection are found to have thoracic aortic dilation, aneurysm, or dissection, referral to a geneticist may be considered. (*Level of evidence: C*)

Recommendations for Bicuspid Aortic Valve and Associated Congenital Variants in Adults

Class I

- First-degree relatives of patients with a bicuspid aortic valve, premature onset of thoracic aortic disease with minimal risk factors, and/or a familial form of thoracic aortic aneurysm and dissection should be evaluated for the presence of a bicuspid aortic valve and asymptomatic thoracic aortic disease. (*Level of evidence: C*)
- All patients with a bicuspid aortic valve should have both the aortic root and ascending thoracic aorta evaluated for evidence of aortic dilation. (*Level of evidence: B*)

REFERENCES, 1330

Peripheral artery disease (PAD) generally refers to a disorder in which blood supply to the lower or upper extremities is obstructed.¹ Most commonly caused by atherosclerosis, PAD may also result from thrombosis, embolism, vasculitis, fibromuscular dysplasia, or entrapment. The term *peripheral vascular disease* is less specific because it encompasses a group of diseases affecting blood vessels that include other atherosclerotic conditions such as renal artery disease and carotid artery disease, as well as vasculitides, vasospasm, venous thrombosis, venous insufficiency, and lymphatic disorders.

PAD correlates strongly with risk for major cardiovascular events because it associates frequently with coronary and cerebral atherosclerosis.² Moreover, symptoms of PAD, including intermittent claudication, jeopardize quality of life and independence for many patients. PAD is commonly underdiagnosed and undertreated; thus practitioners of cardiology have increasing interest in its diagnosis and management. This chapter provides a framework for the diagnosis and management of patients with PAD.

EPIDEMIOLOGY

The prevalence of PAD varies according to the population studied, the diagnostic method used, and whether symptoms are included to derive estimates. Most epidemiologic studies have used a noninvasive measurement, the ankle-brachial index (ABI), to diagnose PAD. The ABI is the ratio of ankle to brachial systolic blood pressure (described in greater detail later). The prevalence of PAD based on abnormal ABI values ranges from approximately 6% in persons 40 years and older to 15% to 20% in those 65 years and older.³⁻⁵ The prevalence of PAD is greater in men than in women in most studies.⁵⁻⁷ Taking into consideration the total number of women and men in the U.S. population, however, there are more women than men with PAD.⁷ Blacks have a higher prevalence of PAD than non-Hispanic whites do.⁴ In MESA (Multi-Ethnic Study of Atherosclerosis), blacks had odds for the development of PAD that was 1.47 times higher than in non-Hispanic whites, whereas in Hispanics and Chinese it was less

than 0.5 times that of non-Hispanic whites.⁸ These aggregate data indicate that some 8 to 10 million individuals in the United States have PAD.

Questionnaires specifically designed to elicit symptoms of intermittent claudication can serve to assess the prevalence of symptomatic disease in these populations. Estimates vary by age and sex but generally indicate that only 10% to 30% of patients with PAD have claudication. Overall, the estimated prevalence of claudication ranges from 1.0% to 4.5% in a population older than 40 years.^{5,6} The prevalence and incidence of claudication increase with age and are greater in men than in women in most studies (**Fig. 58-1**).^{4,5,7} Less information is available on the prevalence and incidence of critical limb ischemia. Its estimated incidence is 500 to 1000 per million population per year, and it affects 1% to 2% of patients with PAD.^{5,6} The incidence of amputation ranges from 112 to 250 per million population per year.

Risk Factors for Peripheral Artery Disease

The well-known modifiable risk factors associated with coronary atherosclerosis also contribute to atherosclerosis of the peripheral circulation (**see Chapter 42**). Cigarette smoking, diabetes mellitus, dyslipidemia, and hypertension increase the risk for PAD (**Table 58-1**). Data from several observational studies indicate a twofold to fourfold increase in the prevalence of PAD in current smokers in comparison to never smokers.⁴ There is a dose-response relationship between lifetime exposure to cigarettes and the incidence of symptomatic PAD. In the Women's Health Study, the hazard ratio for incident symptomatic PAD in smokers of more than 15 cigarettes per day was 17 (95% confidence interval [CI], 11 to 27); the risk decreased following smoking cessation.⁹ Patients with diabetes mellitus often have extensive and severe PAD and a greater propensity for arterial calcification.^{10,11} Involvement of the femoral and popliteal arteries resembles that in nondiabetic persons, but distal disease affecting the tibial and peroneal arteries occurs more frequently. The risk for development of PAD increases twofold to fourfold in patients with diabetes mellitus.⁴ Among patients with PAD, diabetic patients are

more likely than nondiabetic patients to undergo an amputation, and diabetes increases the risk for critical limb ischemia.¹² In NHANES (National Health and Nutrition Examination Survey), insulin resistance was associated with a greater prevalence of PAD,¹³ and patients with metabolic syndrome had an increased risk for the development of symptomatic PAD in the Women's Health Study,¹⁴ but not in the Edinburgh Artery Study.¹⁵ Abnormalities in lipid metabolism also associate with an increased prevalence of PAD. Elevations in total or low-density lipoprotein (LDL) cholesterol increase the risk for development of PAD and claudication in most studies. Hypertriglyceridemia predicts risk for PAD when considered as an independent variable, but its effect diminishes when considered in the context of other lipid fractions.⁴ In addition, hypertension increases the risk for PAD by 1.3- to 2.2-fold.⁴ In the Women's Health Study, incident symptomatic PAD related to the severity of hypertension.¹⁶ Chronic kidney disease also augments PAD.¹⁷

The risk for development of PAD and intermittent claudication increases progressively with the burden of contributing factors.

The pathobiology of PAD involves inflammation, as does atherosclerosis in other beds.¹⁸ High levels of fibrinogen associate with risk not only for coronary events but also for the development of PAD. Current analyses, however, suggest that adjustment for inflammatory markers, such as C-reactive protein, eliminates the risk for PAD associated with fibrinogen. Thus the elevated fibrinogen levels in patients with PAD may reflect inflammation as much as or more than a pro-coagulant effect. Considerable evidence links leukocytes, cells that mediate the inflammatory response, with the development of PAD. Levels of the soluble forms of leukocyte adhesion molecules correlate with the development and extent of PAD and with the risk for complications.^{19,20} Levels of C-reactive protein and monocytes in peripheral blood independently associate with PAD, consistent with a role of innate immunity and chronic inflammation in its pathogenesis.^{21,22} Conversely, serum bilirubin, an endogenous antioxidant with anti-inflammatory properties, associates with reduced PAD prevalence.²³ Inflammation provides the mechanistic link between many of the common risk factors for atherosclerosis and the pathophysiologic processes in the arterial wall that lead to PAD.

Pathophysiology of Peripheral Artery Disease

Pathophysiologic considerations in patients with PAD must take into account the balance of the circulatory supply of nutrients to skeletal muscle and the oxygen and nutrient demand of skeletal muscle (Table 58-2). Intermittent claudication occurs when the oxygen demand of skeletal muscle during effort exceeds the blood's oxygen supply and results from activation of local sensory receptors by accumulation of lactate or other metabolites. Patients with intermittent claudication may have single or multiple occlusive lesions in the arteries supplying the limb. Blood flow and leg oxygen consumption are normal at rest, but the obstructive lesions limit blood flow and oxygen delivery during exercise such that the metabolic needs of the exercising muscle outstrip the available supply of oxygen and nutrients. Patients with critical limb ischemia typically have multiple occlusive lesions that often affect both proximal and distal limb arteries. As a result, even the resting blood supply diminishes and cannot meet the nutritional needs of the limb.

Factors Regulating Blood Supply

Flow through an artery is directly related to perfusion pressure and inversely related to vascular resistance (see Chapter 49). Stenoses reduce flow through the artery (Fig. 58-2), as described in the Poiseuille equation:

$$Q = \frac{\Delta P \pi r^4}{8 \eta l}$$

where ΔP is the pressure gradient across the stenosis, r is the radius of the residual lumen, η is blood viscosity, and l is the length of the

FIGURE 58-1 Age-related prevalence of intermittent claudication derived from large population-based studies. (From Norgren L, Hiatt WR, Dormandy JA, et al: *Inter-Society Consensus for the Management of Peripheral Arterial Disease [TASC II]*. *Eur J Vasc Endovasc Surg* 33:S1, 2007.)

TABLE 58-1 Odds Ratio of Peripheral Artery Disease in Persons with Risk Factors

RISK FACTOR	ODDS RATIO (95% CI)
Cigarette smoking	4.46 (2.25-8.84)
Diabetes mellitus	2.71 (1.03-7.12)
Hypertension	1.75 (0.97-3.13)
Hypercholesterolemia	1.68 (1.09-2.57)
Hyperhomocysteinemia	1.92 (0.95-3.88)
Chronic kidney disease	2.00 (1.08-3.70)
Insulin resistance	2.06 (1.10-4.00)
C-reactive protein	2.20 (1.30-3.60)

Data derived from reports of the National Health and Nutrition Examination (Selvin E, Erlinger TP: Prevalence of and risk factors for peripheral arterial disease in the United States: Results from the National Health and Nutrition Examination Survey, 1999-2000. *Circulation* 110:738, 2004; Pande RL, Perlstein TS, Beckman JA, Creager MA: Association of insulin resistance and inflammation with peripheral arterial disease: The National Health and Nutrition Examination Survey, 1999 to 2004. *Circulation* 118:33, 2008; O'Hare AM, Glidden DV, Fox CS, Hsu CY: High prevalence of peripheral arterial disease in persons with renal insufficiency: Results from the National Health and Nutrition Examination Survey 1999-2000. *Circulation* 109:320, 2004; and Guallar E, Silbergeld EK, Navas-Acien A, et al: Confounding of the relation between homocysteine and peripheral arterial disease by lead, cadmium, and renal function. *Am J Epidemiol* 163:700, 2006.)

TABLE 58-2 Pathophysiologic Considerations in Peripheral Artery Disease

Factors Regulating Blood Supply to Limb
Flow-limiting lesion (stenosis severity, inadequate collateral vessels)
Impaired vasodilation (decreased nitric oxide and reduced responsiveness to vasodilators)
Accentuated vasoconstriction (thromboxane, serotonin, angiotensin II, endothelin, norepinephrine)
Abnormal rheology (reduced red blood cell deformability, increased leukocyte adhesiveness, platelet aggregation, microthrombosis, increased fibrinogen)
Altered Skeletal Muscle Structure and Function
Axonal denervation of skeletal muscle
Loss of type II, glycolytic fast-twitch fibers
Impaired mitochondrial enzymatic activity

FIGURE 58-2 Pathophysiology of intermittent claudication. In healthy arteries (**top**), flow is laminar and endothelial function is normal; therefore blood flow and oxygen delivery match muscle metabolic demand at rest and during exercise. Muscle metabolism is efficient and results in low oxidative stress. In contrast, in PAD (**bottom**), arterial stenosis results in disturbed flow, and the loss of kinetic energy results in a drop in pressure across the stenosis. Collateral vessels have high resistance and only partially compensate for the arterial stenosis. In addition, endothelial function is impaired, thereby resulting in further loss of vascular function. These changes limit the blood flow response to exercise and result in a mismatch of oxygen delivery to muscle metabolic demand. Changes in skeletal muscle metabolism further compromise the efficient generation of high-energy phosphates. Oxidant stress, the result of inefficient oxidation, further impairs endothelial function and muscle metabolism. (From Hiatt WR, Brass EP: *Pathophysiology of intermittent claudication*. In Creager MA, Beckman J, Loscalzo J [eds]: *Vascular Medicine. A Companion to Braunwald's Heart Disease*. 2nd ed. Philadelphia, Elsevier, 2013.)

vessel affected by the stenosis. As the severity of a stenotic lesion increases, flow becomes progressively reduced. The pressure gradient across the stenosis increases in a nonlinear manner, thus emphasizing the importance of a stenosis at high blood flow rates. Usually, a blood pressure gradient exists at rest if the stenosis reduces the diameter of the lumen by more than 50% because as distorted flow develops, kinetic energy is lost. A stenosis that does not cause a pressure gradient at rest may cause one during exercise when blood flow increases as a result of the higher cardiac output and vascular resistance decreases. Consequently, as flow through a stenosis increases, distal perfusion pressure drops. As the metabolic demand of exercising muscle outstrips its blood supply, local metabolites (including adenosine, nitric oxide, potassium, and hydrogen ion) accumulate, and peripheral resistance vessels dilate. Perfusion pressure then drops further because the stenosis limits flow. In addition, intramuscular pressure rises during exercise and may exceed the arterial pressure distal to an occlusion and halt blood flow. Flow through collateral blood vessels can usually meet the resting metabolic needs of skeletal muscle tissue at rest but does not suffice during exercise.

Functional abnormalities in vasomotor reactivity may also interfere with blood flow. Patients with peripheral atherosclerosis have reduced vasodilator capability of both conduit and resistance vessels. Normally, arteries dilate in response to pharmacologic and biochemical stimuli, such as acetylcholine, serotonin, thrombin, and bradykinin, as well as in response to shear stress induced by increases in blood flow. This vasodilator response results from the release of biologically active substances from the endothelium, particularly nitric oxide (see Chapter 49). The vascular relaxation of a conduit vessel that occurs after a flow stimulus, such as that induced by exercise, may facilitate the delivery of blood to exercising muscles in healthy persons. The atherosclerotic femoral arteries and calf resistance vessels of patients with PAD have impaired endothelium-dependent vasodilation in response to flow or pharmacologic stimuli. This failure of vasodilation might prevent an increase in nutritive blood supply to exercising muscle because endothelium-derived nitric oxide can contribute to hyperemic blood flow after an ischemic stimulus.

Abnormalities in the microcirculation also contribute to the pathophysiology of critical limb ischemia. Patients with severe limb ischemia have a reduced number of perfused skin capillaries. Other potential causes of decreased capillary perfusion in this condition include reduced red blood cell deformability, increased leukocyte adhesiveness, platelet aggregates, fibrinogen, microvascular thrombosis, excessive vasoconstriction, and interstitial edema. Intravascular pressure may also decrease because of precapillary arteriolar dilation secondary to locally released vasoactive metabolites.²⁴

Skeletal Muscle Structure and Metabolic Function

Electrophysiologic and histopathologic examination has found evidence of partial axonal denervation of skeletal muscle in legs affected by PAD. Type I, oxidative slow-twitch fibers are preserved, but type II, glycolytic fast-twitch fibers are lost in the skeletal muscle of patients with PAD. The loss of type II fibers correlates with decreased muscle strength and reduced exercise capacity. In skeletal muscle distal to PAD, the shift to anaerobic metabolism occurs earlier during exercise and persists longer after exercise. Patients with claudication have increased lactate release and accumulation of acylcarnitines during exercise and slowed oxygen desaturation kinetics, indicative of ineffective oxidative metabolism.^{24,25} Moreover, mitochondrial respiratory activity and phosphocreatine and adenosine triphosphate (ATP) recovery time are delayed in the calf muscles of PAD patients, as assessed after submaximal exercise by ³¹P magnetic resonance spectroscopy.²⁶

CLINICAL FEATURES

Symptoms

The cardinal symptoms of PAD include intermittent claudication and pain at rest. The term *claudication* is derived from the Latin word *claudicare*, “to limp.” Intermittent claudication refers to a pain, ache, sense of fatigue, or other discomfort that occurs in the affected muscle group with exercise, particularly walking, and resolves with rest. The location of the symptom is often related to the site of the most proximal stenosis. Buttock, hip, or thigh claudication typically occurs in patients with obstruction of the aorta and iliac arteries. Calf claudication is caused by femoral or popliteal artery stenoses. The gastrocnemius muscle consumes more oxygen during walking than other muscle groups in the leg do and hence causes the most frequent symptoms reported by patients. Ankle or foot claudication occurs in patients with tibial and peroneal artery disease. Similarly, stenoses of the subclavian, axillary, or brachial arteries may cause shoulder, biceps, or forearm claudication, respectively. The symptoms should resolve several minutes after cessation of effort. Calf and thigh pain that occurs during rest, such as nocturnal cramps, should not be confused with claudication and is not a symptom of PAD. The history obtained from persons reporting claudication should note the walking distance, speed, and incline that precipitate claudication. Such baseline assessment is used to evaluate disability and provides an initial qualitative measure with which to determine stability, improvement, or deterioration during subsequent encounters with the patient. Symptoms other than claudication can also limit

functional capacity. Patients with PAD walk more slowly and have less walking endurance than do patients without PAD.²⁷

Several questionnaires can be used to assess the presence and severity of claudication. The Rose Questionnaire was developed initially to diagnose both angina and intermittent claudication in epidemiologic surveys. It questions whether pain develops in either calf with walking and whether the pain occurs at rest, while walking at an ordinary or hurried pace, or on walking uphill. Several modifications of this questionnaire have been developed, including the Edinburgh Claudication Questionnaire and the San Diego Claudication Questionnaire,²⁸ both of which are more sensitive and specific than a physician's diagnosis of intermittent claudication based on walking distance, walking speed, and nature of the symptoms. Another validated instrument, the Walking Impairment Questionnaire, asks a series of questions and derives a point score based on walking distance, walking speed, and nature of the symptoms.²⁹

Symptoms resembling limb claudication occasionally result from nonatherosclerotic causes of arterial occlusive disease (**Table 58-3**), including arterial embolism; vasculitides such as thromboangiitis obliterans, Takayasu arteritis, and giant cell arteritis; aortic coarctation; fibromuscular dysplasia; irradiation; endofibrosis of the external iliac artery; and extravascular compression as a result of arterial entrapment or an adventitial cyst (**see Chapter 84**). Several nonvascular causes of exertional leg pain enter into the differential diagnosis of intermittent claudication (see **Table 58-3**). Lumbosacral radiculopathy resulting from degenerative joint disease, spinal stenosis, and herniated discs can cause pain in the buttock, hip, thigh, calf, or foot with walking, often after very short distances or even with standing. This symptom has been called neurogenic pseudoclaudication. Lumbosacral spine disease and PAD both preferentially affect the elderly and hence may coexist in the same individual. Arthritis of the hips and knees also provokes leg pain with walking. Typically, the pain is localized to the affected joint and can be elicited on physical examination by palpation and range-of-motion maneuvers. Exertional compartment syndrome most often occurs in athletes with large calf muscles; increased tissue pressure during exercise limits microvascular flow and results in calf pain or tightness. Symptoms improve after cessation of exercise. Rarely, skeletal muscle disorders such as myositis can cause exertional leg pain. Muscle tenderness, an abnormal finding on neuromuscular examination, elevated skeletal muscle

enzyme levels, and normal findings on pulse examination should distinguish myositis from PAD. Glycogen storage disease type V, also known as McArdle syndrome, in which skeletal muscle phosphorylase is deficient, can cause symptoms mimicking the claudication of PAD. Patients with chronic venous insufficiency sometimes report leg discomfort with exertion, a condition designated venous claudication. Venous hypertension during exercise increases arterial resistance in the affected limb and limits blood flow. In the case of venous insufficiency, elevated extravascular pressure caused by interstitial edema further diminishes capillary perfusion. Peripheral edema, venous stasis pigmentation, and occasionally venous varicosities demonstrated on physical examination will identify this unusual cause of exertional leg pain.

Symptoms may occur at rest in patients with critical limb ischemia. Typically, patients complain of pain or paresthesias in the foot or toes of the affected extremity. This discomfort worsens on leg elevation and improves with leg dependency, as might be anticipated by the effect of gravity on perfusion pressure. The pain can be particularly severe at sites of skin fissuring, ulceration, or necrosis. Frequently, the skin is very sensitive, and even the weight of bedclothes or sheets elicits pain. Patients may sit on the edge of the bed and dangle their legs to alleviate the discomfort. In contrast, patients with ischemic or diabetic neuropathy can experience little or no pain despite the presence of severe ischemia.

Critical limb and digital ischemia can result from arterial occlusions other than those caused by atherosclerosis, including conditions such as thromboangiitis obliterans, vasculitides such as systemic lupus erythematosus or scleroderma, vasospasm, atheromatous embolism, and acute arterial occlusion secondary to thrombosis or embolism (see later). Acute gouty arthritis, trauma, and sensory neuropathy such as that caused by diabetes mellitus, lumbosacral radiculopathies, and complex regional pain syndrome (previously known as reflex sympathetic dystrophy) can cause foot pain. Leg ulcers also occur in patients with venous insufficiency or sensory neuropathy, particularly that related to diabetes. These ulcers appear to be distinct from those caused by arterial disease. The ulcer of venous insufficiency usually localizes near the medial malleolus and has an irregular border and a pink base with granulation tissue. Ulcers attributable to venous disease produce milder pain than do those caused by arterial disease. Neurotrophic ulcers occur at sites of pressure or trauma, usually on the sole of the foot. These ulcers are deep, frequently infected, and not generally painful because of the loss of sensation.

TABLE 58-3 Differential Diagnosis of Exertional Leg Pain

Vascular Causes
Atherosclerosis
Thrombosis
Embolism
Vasculitis
Thromboangiitis obliterans
Takayasu arteritis
Giant cell arteritis
Aortic coarctation
Fibromuscular dysplasia
Irradiation
Endofibrosis of the external iliac artery
Extravascular compression
Arterial entrapment (e.g., popliteal artery entrapment, thoracic outlet syndrome)
Adventitial cysts
Nonvascular Causes
Lumbosacral radiculopathy
Degenerative arthritis
Spinal stenosis
Herniated disc
Arthritis
Hips, knees
Venous insufficiency
Myositis
Glycogen storage disease type V (McArdle syndrome)

Physical Findings

A complete cardiovascular examination includes palpation of the peripheral pulses and auscultation of accessible arteries for bruits (see also Fig. 11-4). Pulse abnormalities and bruits increase the likelihood of PAD.³⁰ Readily palpable pulses in healthy individuals include the brachial, radial, and ulnar arteries in the upper extremities and the femoral, popliteal, dorsalis pedis, and posterior tibial arteries in the lower extremities. The aorta can also be palpated in thin people. A decreased or absent pulse provides insight into the location of arterial stenoses. For example, a normal right femoral pulse but absent left femoral pulse suggests the presence of left iliofemoral arterial stenosis. A normal femoral artery pulse but absent popliteal artery pulse would indicate a stenosis in the superficial femoral artery or proximal popliteal artery. A palpable popliteal artery pulse with absent dorsalis pedis or posterior tibial artery pulses indicate disease of the anterior and posterior tibial arteries, respectively. Bruits are often a sign of accelerated blood flow velocity and flow disturbance at sites of stenosis. A stethoscope should be used to auscultate the supraclavicular and infraclavicular fossae for evidence of subclavian artery stenosis; the abdomen, flank, and pelvis for evidence of stenoses in the aorta and its branch vessels; and the inguinal region for evidence of femoral artery stenoses. Pallor can be elicited on the soles of the feet of some patients with PAD by performing a maneuver in which the feet are elevated above the level of the heart and the calf muscles are exercised by repeated dorsiflexion and plantar

FIGURE 58-3 Typical arterial ulcer. It is a discrete, circumscribed, necrotic ulcer located on the great toe.

flexion of the ankle. The legs are then placed in the dependent position, and the time until the onset of hyperemia and venous distention is measured. Each of these variables depends on the rate of blood flow, which in turn reflects the severity of stenosis and adequacy of collateral vessels.

The legs of patients with chronic aortoiliac disease may show muscle atrophy. Additional signs of chronic low-grade ischemia include hair loss, thickened and brittle toenails, smooth and shiny skin, and atrophy of the subcutaneous fat of the digital pads. Patients with severe limb ischemia have cool skin and may also have petechiae, persistent cyanosis or pallor, dependent rubor, pedal edema resulting from prolonged dependency, skin fissures, ulceration, or gangrene. The ulcers caused by PAD typically have a pale base with irregular borders and usually involve the tips of the toes or the heel of the foot or develop at sites of pressure (Fig. 58-3). These ulcers vary in size and may be as small as 3 to 5 mm.

Categorization

Classification of patients with PAD depends on the severity of the symptoms and abnormalities detected on physical examination. Categorization of the clinical manifestations of PAD improves communication among professionals caring for these patients and provides a structure for defining guidelines for therapeutic interventions. Fontaine described one widely used scheme in which patients are classified into one of four stages progressing from asymptomatic to critical limb ischemia (Table 58-4). Several professional vascular societies have adopted a contemporary, more descriptive classification that includes asymptomatic patients, three grades of claudication, and three grades of critical limb ischemia ranging from rest pain alone to minor and major tissue loss (Table 58-5).³¹

TESTING FOR PERIPHERAL ARTERY DISEASE

Segmental Pressure Measurement

Measurement of systolic blood pressure along selected segments of each extremity is one of the simplest and most useful noninvasive measures for ascertaining the presence and severity of stenoses in the peripheral arteries. In the lower extremities, pneumatic cuffs are placed on the upper and lower portions of the thigh, on the calf, above the ankle, and often over the metatarsal area of the foot. Similarly, for the upper extremities, pneumatic cuffs are placed on the upper part of the arm over the biceps, on the forearm below the elbow, and at the wrist. Systolic blood pressure at each respective

TABLE 58-4 Fontaine Classification of Peripheral Artery Disease

STAGE	SYMPTOMS
I	Asymptomatic
II	Intermittent claudication
IIa	Pain free, claudication walking >200 m
IIb	Pain free, claudication walking <200 m
III	Rest and nocturnal pain
IV	Necrosis, gangrene

TABLE 58-5 Clinical Categories of Chronic Limb Ischemia

GRADE	CATEGORY	CLINICAL DESCRIPTION
	0	Asymptomatic
I	1	Mild claudication
	2	Moderate claudication
	3	Severe claudication
II	4	Ischemic rest pain
	5	Minor tissue loss: nonhealing ulcer, focal gangrene with diffuse pedal ulcer
III	6	Major tissue loss extending above the transmetatarsal level, functional foot no longer salvageable

Modified from Rutherford RB, Baker JD, Ernst C, et al: Recommended standards for reports dealing with lower extremity ischemia: Revised version. *J Vasc Surg* 26:517, 1997.

limb segment is measured by first inflating the pneumatic cuff to suprasystolic pressure and then determining the pressure at which blood flow occurs during deflation of the cuff. The onset of flow is assessed by placing a Doppler ultrasound flow probe over an artery distal to the cuff. In the lower extremities, it is most convenient to place the Doppler probe on the foot over the posterior tibial artery, as it courses inferior and posterior to the medial malleolus, or over the dorsalis pedis artery on the dorsum of the metatarsal arch. In the upper extremities, the Doppler probe can be placed over the brachial artery in the antecubital fossa or over the radial and ulnar arteries at the wrist.

Left ventricular contraction imparts kinetic energy to blood, which is maintained throughout the large and medium-sized vessels. Systolic blood pressure may be higher in the more distal vessels than in the aorta and proximal vessels because of amplification and reflection of blood pressure waves. A stenosis can cause loss of pressure energy as a result of increased frictional forces and disturbance of flow at the site of the stenosis. Approximately 90% of the cross-sectional area of the aorta must be narrowed before a pressure gradient develops. In smaller vessels, such as the iliac and femoral arteries, a 70% to 90% decrease in cross-sectional area will cause a resting pressure gradient sufficient to decrease systolic blood pressure distal to the stenosis. Taking into consideration the precision of this noninvasive method and the variability in blood pressure during even short periods, a blood pressure gradient in excess of 20 mm Hg between successive cuffs is generally used as evidence of arterial stenosis in the lower extremity, whereas a gradient of 10 mm Hg indicates a stenosis between sequential cuffs in the upper extremity. Systolic blood pressure in the toes and fingers is approximately 60% of the systolic blood pressure at the ankle and wrist, respectively, because pressure diminishes further in the smaller distal vessels.

Figure 58-4 provides examples of leg segmental pressure measurements in a patient with left calf claudication. In the right leg there are no pressure gradients between the upper and lower parts of the thigh and between the calf and ankle. In the left leg, pressure

FIGURE 58-4 Segmental pressure measurements in a patient with intermittent claudication of the left calf. A pressure gradient is present between the left upper and lower thigh cuffs, lower thigh and calf cuffs, and calf and ankle cuffs, consistent with multisegmental disease affecting the femoral-popliteal and tibial arteries. The left ABI is 0.56, which is abnormal. Segmental pressure measurements and the ABI in the right leg are normal.

gradients between the upper and lower parts of the thigh, between the lower part of the thigh and calf, and between the calf and ankle indicate stenoses in the superficial femoral and popliteal arteries and in the tibioperoneal arteries.

Ankle-Brachial Index

Determination of the ABI is a simplified application of leg segmental blood pressure measurements that can readily be used at the bedside (see Fig. 58-4 and Fig. 11-4). This index is the ratio of systolic blood pressure measured at the ankle to systolic blood pressure measured at the brachial artery.³² A pneumatic cuff placed around the ankle is inflated to suprasystolic pressure and subsequently deflated while the onset of flow is detected with a Doppler ultrasound probe placed over the dorsalis pedis and posterior tibial arteries, thus denoting ankle systolic blood pressure. Brachial artery systolic pressure can be assessed in a routine manner with either a stethoscope to listen for the first Korotkoff sound or a Doppler probe to listen for the onset of flow during cuff deflation. According to the 2011 American College of Cardiology Foundation/American Heart Association (ACCF/AHA) update of the PAD guidelines, the normal ABI range is 1.00 to 1.40. An ABI value of 0.91 to 0.99 is borderline, and an ABI of 0.90 or less is abnormal.³³ An ABI of 0.90 or lower has a specificity of 83% to 99% and a sensitivity of 69% to 73% in detecting stenoses greater than

50%.³³ The sensitivity of an ABI less than 1.0 approaches 100%. The ABI is often used to gauge the severity of PAD. Patients with symptoms of leg claudication often have ABIs ranging from 0.5 to 0.8, and patients with critical limb ischemia usually have an ABI lower than 0.5. A low ABI is associated with shorter walking distance and lower speed. Less than 40% of patients whose ABI is lower than 0.40 can complete a 6-minute walk.³⁴ In patients with skin ulcerations, ankle pressure below 55 mm Hg would predict poor ulcer healing. Leg blood pressure recordings are not reliable in patients with calcified vessels, as might occur in those with diabetes mellitus or renal insufficiency. Inflation of the pneumatic cuff cannot compress the calcified vessel; the Doppler probe consequently indicates continuous blood flow, even when the pressure exceeds 250 mm Hg. An ABI higher than 1.40 indicates a noncompressible artery.

Treadmill Exercise Testing

Treadmill exercise testing can be used to evaluate the clinical significance of peripheral artery stenoses and provide objective evidence of the patient's walking capacity. The claudication onset time is defined as the time at which symptoms of claudication first develop, and the peak walking time occurs when the patient is no longer able to continue walking because of severe leg discomfort. This standardized and more objective measure of walking capacity supplements the patient's history and provides a quantitative assessment of the patient's disability, as well as a metric for monitoring therapeutic interventions.

Treadmill exercise protocols use a motorized treadmill that incorporates fixed or progressive speeds and angles of incline. A fixed workload test usually maintains a constant grade of 12% and a speed of 1.5 to 2.0 mph. A progressive, or graded, treadmill protocol typically maintains a constant speed of 2 mph while the grade gradually increases by 2% every 2 to 3 minutes. Repeated treadmill test results have better reproducibility with progressive than with constant grade protocols.

Treadmill testing can be used to determine whether arterial stenoses contribute to the patient's symptoms of exertional leg pain. During exercise, blood flow through a stenosis increases as vascular resistance falls in the exercising muscle. According to the Poiseuille equation, described previously, the pressure gradient across the stenosis increases in direct proportion to flow. Thus ankle and brachial systolic blood pressure is measured during resting conditions before treadmill exercise, within 1 minute after exercise, and repeatedly until baseline values are reestablished. Normally, the increase in blood pressure that occurs during exercise should be the same in both the upper and lower extremities, with a constant ABI of 1.0 or greater being maintained. In the presence of peripheral artery stenoses, however, the ABI decreases because the increase in blood pressure observed in the arm is not matched by a comparable increase in ankle blood pressure. A 25% or greater decrease in the ABI after exercise in a patient whose walking capacity is limited by claudication is considered diagnostic and implicates PAD as a cause of the patient's symptoms.

Many patients with PAD also have coronary atherosclerosis. The addition of cardiac monitoring to the exercise protocol may provide adjunctive information about the presence of myocardial ischemia. Claudication can limit attainment of a workload sufficient to increase myocardial oxygen demand and provoke myocardial ischemia. Nonetheless, electrocardiographic changes, particularly during low levels of treadmill exercise, may provide evidence of severe coronary artery disease (CAD).

Pulse Volume Recording

The pulse volume recording graphically illustrates the volumetric change in a segment of the limb that occurs with each pulse. Plethysmographic instruments, typically using strain gauges or pneumatic cuffs, can transduce volumetric changes in the limb, which can be displayed on a graphic recorder. These transducers are strategically placed along the limb to record the pulse volume in its different

segments, such as the thigh, calf, ankle, metatarsal region, and toes or the upper part of the arm, forearm, and fingers. The normal pulse volume contour depends on both local arterial pressure and vascular wall distensibility and resembles a blood pressure waveform. It consists of a sharp systolic upstroke rising rapidly to a peak, a dicrotic notch, and a concave downslope that drops off gradually toward the baseline. The contour of the pulse wave changes distal to a stenosis, with loss of the dicrotic notch, a slower rate of rise, a more rounded peak, and a slower descent. The amplitude becomes lower with increasing severity of disease, and the pulse wave may not be recordable at all in a critically ischemic limb. Segmental analysis of the pulse wave may indicate the location of an arterial stenosis, which probably resides in the artery between a normal and an abnormal pulse volume recording. The pulse volume wave also provides information about the integrity of blood flow when blood pressure measurements cannot be obtained accurately because of noncompressible vessels.

Doppler Ultrasonography

Continuous-wave and pulsed-wave Doppler systems transmit and receive high-frequency ultrasound signals. The Doppler frequency shift caused by moving red blood cells varies directly with the velocity of blood flow. Typically, the perceived frequency shift is between 1 and 20 kHz and is within the audible range of the human ear. Therefore placement of a Doppler probe along an artery enables the examiner to hear whether blood flow is present and the vessel is patent. Processing and graphic recording of the Doppler signal permit a more detailed analysis of the frequency components.

Doppler instruments can be used without or with gray-scale imaging to evaluate an artery for the presence of stenoses. The Doppler probe is positioned at approximately a 60-degree angle over the common femoral, superficial femoral, popliteal, dorsalis pedis, and posterior tibial arteries. The normal Doppler waveform has three components: a rapid forward-flow component during systole, a transient flow reversal during early diastole, and a slow antegrade component during late diastole. The Doppler waveform becomes altered if the probe is placed distal to an arterial stenosis and is characterized by deceleration of systolic flow, loss of the early diastolic reversal, and diminished peak frequencies. Arteries in a limb with critical ischemia may not show any Doppler frequency shift. As with pulse volume recordings, change from a normal to an abnormal Doppler waveform as the artery is interrogated more distally suggests the location of a stenosis.

Duplex Ultrasound Imaging

Duplex ultrasound imaging provides a direct, noninvasive means of assessing both the anatomic characteristics of peripheral arteries and the functional significance of arterial stenoses. The methodology incorporates gray-scale B-mode ultrasound imaging, pulsed Doppler velocity measurements, and color coding of the Doppler shift information (Fig. 58-5). Real-time ultrasonographic scanners emit and receive high-frequency sound waves, typically ranging from 2 to 10 MHz, to construct an image. The acoustic properties of the vascular wall differ from those of the surrounding tissue, thus enabling them to easily be imaged. Atherosclerotic plaque may be present and visible on gray-scale images. Pulsed-wave Doppler systems emit ultrasound beams at precise times and can therefore sample the reflected ultrasound waves at specific depths to enable the examiner to determine blood cell velocity within the lumen of the artery. By positioning the pulsed Doppler beam at a known angle, the examiner can calculate blood flow velocity according to the equation

$$Df = 2VF \cos \theta / C$$

where Df is the frequency shift, V is the velocity, F is the frequency of the transmitted sound, θ is the angle between the transmitted sound and the velocity vector, and C is the velocity of sound and tissue. For optimal measurements, the angle of the pulsed Doppler

FIGURE 58-5 Duplex ultrasonogram of the common femoral artery (CFA) bifurcation into the superficial femoral artery (SFA) and deep femoral artery. The **upper image** shows a normal gray-scale image of the artery in which the intima is not thickened and the lumen is widely patent. The **lower image** is a recording of the pulse Doppler velocity sampled from the superficial femoral artery. The triphasic profile is apparent, the envelope is thin, and peak systolic velocity is within normal limits.

beam should be less than 60 degrees. With color Doppler, the frequency shift information within the entire field sampled by the ultrasound beam can be superimposed on the gray-scale image. This approach provides a composite real-time display of flow velocity within the vessel.

Color-assisted duplex ultrasound imaging is an effective means of localizing peripheral arterial stenoses (Fig. 58-6). Normal arteries have laminar flow, with the highest velocity occurring at the center of the artery. The corresponding color image is usually homogeneous with relatively constant hue and intensity. In the presence of an arterial stenosis, blood flow velocity increases through the narrowed lumen. As the velocity increases, there is progressive desaturation of the color display, and flow disturbance distal to the stenosis causes changes in hue and color. Pulsed Doppler velocity measurements can be made along the length of the artery and particularly at areas of flow abnormalities suggested by the color images. A twofold or greater increase in peak systolic velocity at the site of an atherosclerotic plaque indicates a 50% or greater stenosis (see Fig. 58-6). A threefold increase in velocity suggests a 75% or greater stenosis. An occluded artery generates no Doppler signal. With contrast-enhanced angiography as a reference standard, duplex ultrasound imaging for identification of sites of arterial stenosis has approximately 89% to 99% specificity and 80% to 98% sensitivity.^{35,36}

Magnetic Resonance Angiography

Magnetic resonance angiography (MRA) can be used to noninvasively visualize the aorta and peripheral arteries (see Chapters 17 and 60). Resolution of the vascular anatomy with gadolinium-enhanced MRA approaches that of conventional contrast-enhanced digital subtraction angiography (Fig. 58-7). A meta-analysis of 32 studies comparing MRA with intra-arterial digital subtraction

angiography found a pooled sensitivity for MRA of 94.7% (95% CI, 92.1% to 96.4%) and a pooled specificity of 95.6% (95% CI, 94.0% to 96.8%) for detecting segmental stenotic and occlusive lesions.³⁷

MRA currently has its greatest usefulness in the evaluation of symptomatic patients to assist in decision making before endovascular and surgical intervention or in patients at risk for renal, allergic, or other complications during conventional angiography.

Computed Tomographic Angiography

New computed tomography scanners use multidetector technology to acquire cross-sectional images (see Chapter 18). This advance permits imaging of peripheral arteries with excellent spatial resolution during a relatively short time and with a reduced amount of radiocontrast material (Fig. 58-8). Image reconstructions in three

dimensions permit rotation to optimize visualization of arterial stenoses. When compared with conventional contrast-enhanced angiography, the sensitivity and specificity for stenoses greater than 50% or occlusion reported for computed tomographic angiography (CTA) using multidetector technology are 95% (95% CI, 92% to 97%) and 96% (95% CI, 93% to 97%), respectively.³⁸ CTA offers advantages over MRA in that it can be used in patients with stents, metal clips, and pacemakers, although it has the disadvantage of requiring radiocontrast material and ionizing radiation.

Contrast-Enhanced Angiography

Conventional angiography can aid in evaluation of the arterial anatomy before a revascularization procedure. It still has occasional usefulness when the diagnosis is in doubt. Most contemporary

FIGURE 58-6 Duplex ultrasonogram of the external iliac artery. The **upper image** is a color image of the artery in which there is heterogeneity and desaturation of color, indicative of high-velocity flow through a stenosis. The **lower image** is a recording of the pulse Doppler velocity sampled from the right external iliac artery. The peak velocity of 350 cm/sec is elevated. These features are consistent with a significant stenosis.

FIGURE 58-8 CTA in a patient with complete occlusion of the aorta and both iliac arteries. The common femoral arteries have been reconstituted. (Courtesy of the 3D and Image Processing Center of Brigham and Women's Hospital, Boston, Mass.)

FIGURE 58-7 Gadolinium-enhanced two-dimensional MRA of the aorta and both legs extending from the thighs to above the ankle. **A**, Aortiliac atherosclerosis with a stenosed left common iliac artery. **B**, Bilateral superficial femoral artery occlusion with reconstitution of the distal portion of the right and left superficial femoral arteries. **C**, The anterior tibial, posterior tibial, and peroneal arteries, which are patent in each leg.

angiography laboratories use digital subtraction techniques after intra-arterial administration of contrast material to enhance resolution. Injection of the radiocontrast material into the aorta permits visualization of the aorta and iliac arteries, and injection of contrast material into the iliofemoral segment of the involved leg permits optimal visualization of the femoral, popliteal, tibial, and peroneal arteries (**Fig. 58-9**). In patients with aortic occlusion, catheterization of the femoral arteries is not feasible. The aorta can be approached by brachial or axillary artery cannulation or, if necessary, directly via a translumbar approach.

PROGNOSIS

Patients with PAD have increased risk for adverse cardiovascular events, as well as for limb loss and impaired quality of life.^{2,4,6,27} Such patients frequently have concomitant CAD and cerebrovascular disease.^{5,6} The relative prevalence of each of these manifestations of atherosclerosis depends in part on the criteria used to establish the diagnosis. Patients with abnormal ABIs are twofold to fourfold more likely than those with normal ABIs to have a history of myocardial infarction (MI), angina, congestive heart failure, or cerebrovascular ischemia.^{5,6} Angiographically significant CAD occurs in approximately 60% to 80% of patients with PAD,⁶ and 15% to 25% of patients

with PAD have significant carotid artery stenoses as detected by duplex ultrasonography. Two international registries have detected a high prevalence of concomitant CAD and cerebrovascular disease in patients with PAD. In the REACH (Reduction of Atherothrombosis for Continued Health) registry, 62% of the patients had either or both coronary and cerebrovascular disease.³⁹ Approximately 25% of the patients with PAD had a history of MI, 30% had angina, 16% had a previous stroke, and 15% had a previous transient ischemic attack. In the AGATHA (A Global Atherothrombosis Assessment) registry, approximately 50% of the patients with PAD had established CAD and 50% had previous stroke, transient ischemic attack, or carotid artery revascularization.⁴⁰ The specificity of an abnormal ABI in predicting future cardiovascular events is approximately 90%.^{32,41} The risk for death from cardiovascular causes increases 2.5- to 6-fold in patients with PAD, and their annual mortality rate is 4.3% to 4.9%.^{5,6,42,43} Those with the most severe PAD have the greatest risk for death, and mortality correlates with decreasing ABI (**Fig. 58-10**).^{32,44,45} Approximately 25% of patients with critical limb ischemia die within 1 year, and the 1-year mortality rate in patients who have undergone amputation for PAD may be as high as 45%.⁵

Worsening symptoms develop in approximately 25% of patients with claudication. Clinical progression occurs in 7% to 9% of patients with claudication in the first year after diagnosis and in approximately 2% to 3% each year thereafter.^{5,6} Moreover, loss of mobility

FIGURE 58-9 Angiogram of a patient with disabling left calf claudication. **A**, The aorta and bilateral common iliac arteries are patent. **B**, The left superficial femoral artery has multiple stenotic lesions (arrows). Significant stenosis of the left tibioperoneal trunk and left posterior tibial artery (arrows) is present.

occurs more commonly in patients with PAD than in those without PAD, even in patients without classic symptoms of claudication.⁴⁶ Both smoking and diabetes mellitus independently predict progression of disease.^{5,6} Those with diabetes mellitus have at least a 12-fold higher likelihood of amputation than nondiabetic persons do.⁴⁷ The risk for limb loss is higher in PAD patients with critical limb ischemia in whom revascularization fails or is not feasible and approximates 40% by 6 months.⁵

TREATMENT

Treatment of PAD aims to reduce cardiovascular morbidity and mortality, as well as improve quality of life by decreasing symptoms of claudication, eliminating rest pain, and preserving limb viability. Therapeutic considerations therefore include modification of risk factors by alterations in lifestyle and use of pharmacologic therapy to reduce the risk for adverse cardiovascular events such as MI, stroke, and death. Symptoms of claudication can improve with pharmacotherapy or exercise rehabilitation. Optimal management of critical limb ischemia often includes endovascular interventions or surgical reconstruction to improve blood supply and maintain limb viability. Revascularization is also indicated in some patients with disabling symptoms of claudication that persist despite exercise therapy and pharmacotherapy.^{5,6}

Risk Factor Modification

Lipid-lowering therapy can reduce the risk for adverse cardiovascular events (see Chapters 42 and 45). The Heart Protection Study found that lipid-lowering therapy with simvastatin reduced the risk for adverse cardiovascular outcomes by 25% in patients with atherosclerosis, including more than 6700 patients with PAD.⁴⁸ Pooled results from 17 lipid-lowering trials found that lipid-lowering therapy reduced the risk for cardiovascular events in patients with PAD by 26%.⁴⁹ Thus the ACCF/AHA PAD guidelines and the European Society of Cardiology (ESC) PAD guidelines recommend that patients with PAD receive diet and drug therapy to achieve a target LDL cholesterol level of 100 mg/dL or less.^{6,50} Also, several prospective trials have found that statins improve walking distance in patients with PAD. In the TREADMILL (Treatment of Peripheral Atherosclerotic Disease with Moderate

or Intensive Lipid Lowering) trial, atorvastatin (80 mg) increased pain-free walking distance by more than 60% versus a 38% increase with placebo, and additional trials support these findings.⁵¹ Yet in one study the combination of lovastatin and niacin did not improve walking distance over diet alone.⁵² Current evidence has not established that other lipid-lowering therapies (such as niacin, ezetimibe, or fibrates) reduce the risk for cardiovascular events in patients with PAD. In the FIELD (Fenofibrate and Event Lowering Intervention in Diabetes) study, fenofibrate reduced the risk for minor amputation, primarily in patients who did not have known PAD.⁵³

Smoking Cessation

Prospective trials examining the benefits of smoking cessation are lacking, but observational evidence unequivocally shows that cigarette smoking increases the risk for atherosclerosis and its clinical sequelae. Nonsmokers with PAD have lower rates of MI and mortality than do those who have smoked or continue to smoke, and PAD patients who discontinue smoking have approximately twice the 5-year survival rate of those who continue to smoke.⁵⁴ Smoking cessation also lowers risk for the development of critical limb ischemia. In addition to frequent physician advice, pharmacologic interventions that effectively promote smoking cessation include nicotine replacement therapy, bupropion, and varenicline.⁵⁵ The ACCF/AHA PAD guidelines recommend that patients with PAD receive advice to stop smoking and comprehensive smoking cessation instruction, including behavior modification and pharmacologic treatment.³³

Treatment of Diabetes

Aggressive treatment of diabetes decreases the risk for microangiopathic events such as nephropathy and retinopathy (see Chapter 61), but current data fail to support the notion that aggressive treatment of diabetes with glucose-lowering agents favorably affects the clinical manifestations and outcomes of atherosclerosis in general and of PAD in particular.¹² A meta-analysis of five prospective randomized controlled trials found that intensive glycemic control results in a 17% reduction in nonfatal MI events and a 15% reduction in coronary heart disease events, but it had no significant effect on stroke or all-cause mortality.⁵⁶ Among the individual trials included in this meta-analysis, in the ACCORD (Action to Control Cardiovascular Risk in Diabetes) study, intensive glucose control versus placebo did not reduce the primary composite endpoint of nonfatal MI, nonfatal stroke, or cardiovascular death⁵⁷ but it did increase the risk for death and decreased the risk for nonfatal MI, which were secondary outcome measures. In the ADVANCE (Action in Diabetes and Vascular Disease: Preterax and Diamicon Modified Release Controlled Evaluation) study, intensive glucose control did not affect macrovascular events, including death.⁵⁸ In VADT (Veterans Affairs Diabetes Trial), intensive glucose control did not affect the primary composite endpoint of MI, stroke, cardiovascular death, congestive heart failure, revascularization, and amputation for ischemic gangrene.⁵⁹ The PROactive (Prospective Pioglitazone Clinical Trial in Macrovascular Events) study assessed the effect of pioglitazone versus placebo on a broad range of cardiovascular endpoints in patients with type 2 diabetes and established atherosclerosis, including CAD, cerebrovascular disease, and PAD, and found no significant benefit of pioglitazone on the primary outcome.^{56,60}

FIGURE 58-10 Association of ABI with all-cause mortality in a meta-analysis of 16 cohort studies. (From Fowkes FG, Murray GD, Butcher I, et al: Ankle brachial index combined with Framingham Risk Score to predict cardiovascular events and mortality: A meta-analysis. *JAMA* 300:197, 2008.)

In patients with no PAD at baseline, composite primary and secondary event rates were lower with pioglitazone than with placebo treatment. In the PAD patients, however, pioglitazone did not affect these cardiovascular events.⁶¹ Long-term follow-up of the UKPDS (United Kingdom Prospective Diabetes Study) of patients with type 2 diabetes mellitus found that intensive treatment with sulfonylureas or insulin associated with a 15% reduction in MI but no decrease in the incidence of PAD.⁶² Current guidelines variably recommend that patients with PAD and diabetes be treated with glucose-lowering agents to achieve a hemoglobin A1c level of either less than 6.5% or less than 7.0%.^{6,50,63}

Blood Pressure Control

Antihypertensive therapy reduces the risk for stroke, CAD, and vascular death (see also Chapters 42 and 44). Intensive blood pressure control (versus moderate blood pressure control) may reduce cardiovascular events in diabetic patients with PAD.¹² The ACCORD study of patients with diabetes at high risk for cardiovascular events showed no difference in cardiovascular outcomes between intensive antihypertensive therapy to achieve a systolic blood pressure of less than 120 mm Hg and standard therapy to a target systolic blood pressure of less than 140 mm Hg.⁶⁴ In the ADVANCE trial, treatment with perindopril and indapamide lowered blood pressure and reduced macrovascular and microvascular events, including death from cardiovascular disease.⁶⁵ It is not known whether antihypertensive therapy limits the progression of PAD. Treatment of hypertension might decrease perfusion pressure to extremities already compromised by peripheral artery stenoses. In addition, beta-adrenergic receptor blocking agents (beta blockers) might theoretically reduce peripheral blood flow and symptoms of claudication or critical limb ischemia. Yet a systematic review that included six studies of beta blocking agent therapy versus placebo found no significant impairment of walking capacity in a total of 119 patients with intermittent claudication.⁶⁶ Beta blocking agents improve symptoms and reduce the risk for MI and death in patients with CAD, a problem affecting many patients with PAD. Thus if clinically indicated for other conditions, these drugs should not be withheld in patients with PAD.

Angiotensin-converting enzyme inhibitors reduce cardiovascular events in patients with atherosclerosis. In the HOPE (Heart Outcomes Prevention Evaluation) study, the angiotensin-converting enzyme inhibitor ramipril decreased the risk for vascular death, MI, or stroke by 22%.⁶⁷ Forty-four percent of the patients enrolled in the HOPE trial had evidence of PAD, as manifested by an ABI lower than 0.9. In ONTARGET (Ongoing Telmisartan Alone and in Combination with Ramipril Global Endpoint Trial), which included patients with vascular disease or diabetes, the effect of telmisartan and ramipril on the composite endpoint of cardiovascular death, MI, stroke, or hospitalization for heart failure was similar.⁶⁸ More than 13% of the patients in ONTARGET had PAD. Current recommendations are that patients with PAD and hypertension receive blood pressure-lowering agents to achieve a target blood pressure of 140/90 mm Hg or lower.^{6,69}

Antiplatelet Therapy

Substantial evidence supports the use of antiplatelet agents to reduce the incidence of adverse cardiovascular outcomes in patients with atherosclerosis (see Chapter 82). A meta-analysis that systematically reviewed 12 studies comprising 12,168 patients with intermittent claudication found that antiplatelet agents reduced cardiovascular mortality by 46% but did not significantly reduce total cardiovascular events.⁷⁰ In addition, there was a 30% reduction in peripheral revascularization procedures when pooling the results of five trials. Most of the PAD trials in this report, however, included antiplatelet therapy other than aspirin. A meta-analysis that included 18 prospective, randomized controlled trials comprising 5269 persons with PAD found that aspirin therapy did not confer significant reductions in all-cause or cardiovascular mortality, MI, or major bleeding when compared with placebo.⁷¹ Included in this analysis was the POPADAD (Prevention of Progression of Arterial Disease and Diabetes) trial of diabetic

patients with asymptomatic PAD, which found that aspirin did not decrease the risk for a composite primary endpoint that included death from coronary heart disease or stroke, nonfatal MI or stroke, or amputation above the ankle for critical limb ischemia.⁷² In an additional study (the Aspirin for Asymptomatic Atherosclerosis trial), of the 3350 participants with an ABI of 0.95 or lower, aspirin (100 mg daily) did not significantly reduce vascular events more than placebo did.⁷³ The CAPRIE (Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events) trial compared clopidogrel with aspirin for efficacy in preventing ischemic events in patients with recent MI, recent ischemic stroke, or PAD. Overall, an 8.7% reduction in relative risk for MI, ischemic stroke, or vascular death was reported in the group treated with clopidogrel.⁷⁰ Notably, among the 6452 patients in the PAD subgroup, clopidogrel treatment reduced adverse cardiovascular events by 23.8%. The CHARISMA (Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance) trial compared the efficacy of dual antiplatelet therapy consisting of clopidogrel plus aspirin with aspirin alone in patients with established CAD, cerebrovascular disease, or PAD, as well as in patients with multiple atherosclerotic risk factors.⁷⁴ Overall, dual antiplatelet therapy produced no significant benefit over aspirin alone on the primary efficacy endpoint, a composite of MI, stroke, or cardiovascular death. Among the 3096 patients with PAD in the CHARISMA trial, dual antiplatelet therapy reduced rates of MI and hospitalization for ischemic events (Fig. 58-11).⁷⁵ In the CASPAR (Clopidogrel and Acetylsalicylic acid in Peripheral Artery) trial, the combination of clopidogrel and aspirin versus aspirin alone did not affect the primary composite endpoint of graft occlusion, revascularization, amputation, or death in patients undergoing below-knee bypass surgery for PAD.⁷⁶ In the TRA2°P-TIMI 50 trial, vorapaxar, a novel antagonist of protease-activated receptor-1, a receptor present on platelets, endothelium, and vascular smooth muscle, reduced the risk for MI, stroke, and cardiovascular death by 12% in patients with established atherosclerosis, including previous MI, stroke, or PAD.⁷⁷ Among the patients with PAD in the study, vorapaxar significantly reduced the rates of hospitalization for acute limb ischemia and peripheral artery revascularization.⁷⁸ The WAVE (Warfarin Antiplatelet Vascular Evaluation) trial compared combination antiplatelet and oral anticoagulant therapy with antiplatelet therapy alone in patients with PAD.⁷⁹ The two treatments did not differ significantly in the primary composite endpoint of MI, stroke, or cardiovascular death, but life-threatening bleeding occurred more frequently in patients receiving combination

FIGURE 58-11 The effect of clopidogrel plus aspirin versus placebo plus aspirin on the rate of the composite endpoint (cardiovascular death, MI, or stroke), cardiovascular death, MI, stroke, and hospitalization (for unstable angina, transient ischemic attack, or a revascularization procedure). (From Cacoub PP, Bhatt DL, Steg PG, et al: Patients with peripheral arterial disease in the CHARISMA trial. *Eur Heart J* 30:192, 2009.)

antiplatelet and anticoagulant therapy. Current guidelines recommend that symptomatic patients with PAD be treated with an antiplatelet drug, such as aspirin or clopidogrel, to reduce adverse cardiovascular events.^{33,50} Oral anticoagulation with warfarin is not recommended to reduce cardiovascular events in patients with PAD because it is no more effective than antiplatelet therapy and confers a higher risk for bleeding.

Pharmacotherapy

The development of effective pharmacotherapy for symptoms of PAD has lagged substantially behind drug treatment of CAD. Most studies of vasodilator therapy have failed to demonstrate any efficacy in patients with intermittent claudication. Several pathophysiologic explanations may account for the failure of vasodilator therapy in patients with PAD. During exercise, resistance vessels distal to a stenosis dilate in response to ischemia. Vasodilators would have minimal if any effect on these endogenously dilated vessels but would decrease resistance in other vessels and create a relative steal phenomenon and thereby reduce blood flow and perfusion pressure to the affected leg. Moreover, in contrast to their effects on myocardial oxygen consumption in patients with CAD (because of afterload reduction), vasodilators do not reduce skeletal muscle oxygen demand.

The U.S. Food and Drug Administration (FDA) has approved two drugs, pentoxifylline (Trental) and cilostazol (Pletal), for the treatment of claudication in patients with PAD. Licensing bodies in Europe, Asia, and South America have approved additional drugs. Pentoxifylline is a xanthine derivative used to treat patients with intermittent claudication. Its action may be mediated through its hemorheologic properties, including its ability to decrease blood viscosity and to improve erythrocyte flexibility. It may have anti-inflammatory and antiproliferative effects. Pentoxifylline has marginal efficacy^{5,6}; it increased maximum walking distance by only 14% versus placebo in one study.⁸⁰ Cilostazol is a quinolinone derivative that inhibits phosphodiesterase 3, thereby decreasing degradation of cyclic adenosine monophosphate and increasing its concentration in platelets and blood vessels. Although cilostazol inhibits platelet aggregation and causes vasodilation in experimental animals, its mechanism of action in patients with PAD is not known. Meta-analyses of multiple trials have found that cilostazol improves absolute claudication distance by 40% to 50% in comparison to placebo (Fig. 58-12).^{81,82} Quality-of-life measures, as assessed by the 36-Item Short-Form Medical Outcomes Scale (SF-36) and Walking Impairment Questionnaire, also demonstrated improvement. An FDA advisory stated that cilostazol should not be used in patients with congestive heart failure because other phosphodiesterase 3 inhibitors have been shown to decrease survival in these patients. A long-term safety trial found that cilostazol (versus placebo) did not

increase the risk for total or cardiovascular mortality, but the study was limited because more than 60% of the patients discontinued treatment before completion of the study.⁸³ The ACCF/AHA PAD guidelines recommend cilostazol to improve symptoms and walking distance in patients with PAD.⁶

Other classes of drugs—including statins, angiotensin-converting enzyme inhibitors, serotonin (5-HT₂) antagonists, alpha-adrenergic antagonists, L-arginine, carnitine derivatives, vasodilator prostaglandins, antibiotics, and angiogenic growth factors—have been studied or are currently under investigation for the treatment of either claudication or critical limb ischemia.⁵⁴ As noted previously, several trials have found that statins improve walking distance in patients with PAD. One group of investigators reported that the angiotensin-converting enzyme inhibitor ramipril improves maximal walking time in patients with claudication.⁸⁴ Naftidrofuryl, a serotonin antagonist, improved symptoms of claudication in some trials and is currently available for use in Europe.⁵ Selective serotonin 2A antagonists have not been effective in improving claudication distance.^{85,86} One study found that buflomedil, a drug with adrenergic receptor antagonist properties, decreased the risk for critical cardiovascular events—defined as the composite of cardiovascular death, nonfatal MI, nonfatal stroke, symptomatic deterioration of PAD, or leg amputation—by 26% in comparison to placebo in patients with claudication.⁸⁷ L-Arginine, the precursor for endothelium-derived nitric oxide, has not proved useful in improving PAD symptoms.⁸⁸ Propionyl-L-carnitine, a cofactor for fatty acid metabolism, improved claudication in some studies but not in others.⁸⁹ Prostacyclin analogues did not improve walking time in patients with intermittent claudication.⁹⁰ The antichlamydial agent rifalazil did not improve walking time in patients with claudication in comparison to placebo.⁹⁰

Angiogenic growth factors have yielded encouraging preliminary findings in patients with critical limb ischemia.⁹¹⁻⁹³ However, nonviral fibroblast growth factor delivered by intramuscular injection did not reduce the rate of amputation-free survival in patients with critical limb ischemia in a phase III placebo-controlled trial.⁹⁴ Placebo-controlled clinical trials of angiogenic growth factors in patients with claudication have not shown improvement in walking time.^{95,96} In initial reports, stem cell–based therapies for PAD have been found to improve ABI, rest pain, and pain-free walking time and prevent amputation in patients with chronic limb ischemia.^{54,97,98} These findings require confirmation with additional clinical trials.

Exercise Rehabilitation

Supervised exercise rehabilitation programs improve symptoms of claudication in patients with PAD (see Chapter 47). Meta-analyses of controlled studies of exercise rehabilitation have found that supervised walking programs increase the average maximal distance walked by 50% to 200% (Fig. 58-13).⁹⁹ The greatest benefit occurs when sessions are at least 30 minutes in duration, when sessions take place at least three times per week for 6 months, and when walking is the mode of exercise. Home-based exercise training, when governed with a step-activated monitor, also improved walking time in patients with claudication.¹⁰⁰ Leg strength training improves walking time, although not as much as treadmill exercise training does.¹⁰¹ Arm ergometry also improves walking performance.¹⁰² In the CLEVER (Claudication Exercise versus Endoluminal Revascularization) trial of patients with iliac artery stenosis, supervised exercise training improved mean walking time more than endovascular intervention did, and both were more effective than optimal medical therapy; however, quality-of-life measures improved more in the endovascular intervention group¹⁰³ (Fig. 58-14). Postulated mechanisms through which exercise training improves claudication include the formation of collateral vessels and improvement in endothelium-dependent vasodilation, hemorheology, muscle structure and metabolism, and walking efficiency. Exercise increases the expression of angiogenic factors, particularly in hypoxic tissue.^{104,105} Exercise training also improves endothelium-dependent vasodilation in patients with PAD. Improvement in calf blood flow has not been demonstrated consistently in patients with claudication, however.¹⁰⁶ A recent study found that exercise training increased capillary density in calf muscle and that this change preceded the improvement in maximal oxygen consumption.¹⁰⁷ To date, no imaging studies have demonstrated increased collateral blood vessels after exercise training in patients with PAD.

FIGURE 58-12 Effect of cilostazol versus placebo on maximal walking distance based on a meta-analysis of nine randomized trials. (Modified from Pande RL, Hiatt WR, Zhang P, et al: A pooled analysis of the durability and predictors of treatment response of cilostazol in patients with intermittent claudication. *Vasc Med* 15:181, 2010.)

FIGURE 58-13 Meta-analysis of the effect of exercise training versus usual care on maximum walking distance in patients with intermittent claudication. (From Watson L, Ellis B, Leng GC: Exercise for intermittent claudication. *Cochrane Database Syst Rev* [4]:CD000990, 2008.)

FIGURE 58-14 Effect of optimal medical care (OMC), exercise training, and endovascular intervention on peak walking time at 6 months in patients with iliac artery stenosis. Supervised exercise training improved mean walking time more than endovascular intervention did, and both were more effective than OMC. (Modified from Murphy TP, Cutlip DE, Regensteiner JG, et al: Supervised exercise versus primary stenting for claudication resulting from aortoiliac peripheral artery disease: six-month outcomes from the Claudication: Exercise Versus Endoluminal Revascularization [CLEVER] study. *Circulation*;125:130, 2012.)

The benefits of exercise training in patients with PAD may result from changes in skeletal muscle structure or function, such as increased muscle mitochondrial enzyme activity, oxidative metabolism, and ATP production rate. In patients with PAD, improvement in exercise performance is associated with a decrease in plasma and skeletal muscle short-chain acylcarnitine concentrations, which indicates improvement in oxidative metabolism and increased peak oxygen consumption. Higher physical activity levels in patients with PAD are associated with greater calf muscle area and density.³⁴ Training may also enhance biomechanical performance and enable patients to walk more efficiently with less energy expenditure. Current guidelines recommend that patients with intermittent claudication undergo supervised exercise rehabilitation as initial therapy.^{33,50} Supervised exercise training should consist of 30- to 60-minute sessions at least three times per week for a minimum of 12 weeks.^{5,50}

Percutaneous Transluminal Angioplasty and Stents

Peripheral catheter-based interventions are indicated for patients with lifestyle-limiting claudication despite a trial of exercise rehabilitation

or pharmacotherapy (see Chapter 60).^{5,6,108,109} Endovascular intervention should be considered in symptomatic patients with clinical evidence of inflow disease as manifested by buttock or thigh claudication and diminished femoral pulses. Patients with critical limb ischemia whose anatomy is amenable to catheter-based therapy should also undergo endovascular intervention.

Peripheral Artery Surgery

Surgical revascularization generally improves quality of life in patients with disabling claudication despite maximal medical therapy and is indicated to relieve rest pain and preserve limb viability in patients with critical limb ischemia that is not amenable to percutaneous interventions. The specific operation must take into account the anatomic location of the arterial lesions and the presence of comorbid conditions. Planning for surgical procedures requires identification of the arterial obstruction by imaging to ensure sufficient arterial inflow to and outflow from the graft to maintain patency. Preoperative evaluation to assess the risk associated with vascular surgery should be performed because many of these patients have coexisting CAD. Guidelines for such evaluation exist (see Chapter 80).^{110,111}

Aortobifemoral bypass is the most frequent operation performed in patients with aortoiliac disease. Typically, a knitted or woven prosthesis made of Dacron or polytetrafluoroethylene (PTFE) is anastomosed proximally to the aorta and distally to each common femoral artery.^{112,113} On occasion the iliac artery is used for the distal anastomosis to maintain antegrade flow into at least one hypogastric artery. A systematic review of 29 studies from 1970 to 2007 that compared 5738 patients who underwent aortobifemoral bypass surgery found an operative mortality rate of 4%,¹¹⁴ although high-volume centers in the United States report lower mortality rates.¹¹⁵ Five-year patency rates for aortobifemoral bypass grafts exceed 80%.¹¹³

Extra-anatomic surgical reconstructive procedures for aortoiliac disease include axillobifemoral bypass, iliofemoral bypass, and femoral-femoral bypass. These bypass grafts, made of Dacron or PTFE, circumvent the aorta and iliac arteries and are generally used in high-risk patients with critical limb ischemia. Long-term patency rates are inferior to those of aortobifemoral bypass procedures. Five-year patency rates range from 50% to 70% for axillobifemoral bypass operations and from 70% to 80% for femoral-femoral bypass grafts.⁶ The operative mortality rate for extra-anatomic bypass procedures is 3% to 5% and reflects, in part, the serious comorbid conditions and advanced atherosclerosis in many of the patients who undergo these procedures.

Reconstructive surgery for infrainguinal arterial disease includes femoral-popliteal and femoral-tibial or femoral-peroneal artery bypass. Infrainguinal bypass uses in situ or reversed autologous saphenous veins or synthetic grafts made of PTFE as conduits. Patency rates for autologous saphenous vein bypass grafts exceed those with PTFE grafts.^{5,6,113} Grafts with the distal anastomosis placed in the popliteal artery above the knee have better patency rates than do those placed below the knee.⁵ Five-year primary patency rates for femoral-popliteal reconstruction in patients with claudication are approximately 80% and 75% for autogenous vein grafts and PTFE grafts, respectively, and approximately 65% and 45%, respectively, in patients with critical limb ischemia. For femoral below-knee bypass, including tibioperoneal artery reconstruction, the 5-year patency rates for saphenous vein grafts in patients with claudication or critical limb ischemia are similar to those for femoral-popliteal above-knee grafts (60% to 80%). The 5-year patency rate for PTFE grafts in the infrapopliteal position is considerably lower, approximately 65% in patients with claudication and 33% in patients with critical limb ischemia. The operative mortality rate for infrainguinal bypass operations is 2% to 3%.¹¹²

Graft stenoses can result from technical errors at the time of surgery, such as retained valve cuffs or intimal flap or valvotome injury; from fibrous intimal hyperplasia, usually within 6 months of surgery; or from atherosclerosis, which usually occurs within the vein graft at least 1 to 2 years after surgery. Institution of graft surveillance protocols with the use of color-assisted duplex ultrasonography has enabled the identification of graft stenoses, thereby prompting graft

revision and avoiding complete graft failure.^{6,113} Routine ultrasonographic surveillance improves graft outcome. Antithrombotic agents, including antiplatelet drugs and coumarin derivatives, also improve graft patency. Several studies have suggested that antiplatelet drugs may be more effective in preserving synthetic grafts whereas coumarin derivatives may be more effective for vein bypass grafts.^{116,117}

Algorithm for Treatment of the Symptomatic Leg

Figure 58-15 provides a management algorithm for the treatment of intermittent claudication.

VASCULITIS

(See Chapter 84.)

THROMBOANGIITIS OBLITERANS

Thromboangiitis obliterans (TAO), a segmental vasculitis that involves the distal arteries, veins, and nerves of the upper and lower extremities, typically affects younger persons who smoke.^{118,119}

Pathology and Pathogenesis

TAO primarily affects the medium and small vessels of the arms, including the radial, ulnar, palmar, and digital arteries, and their

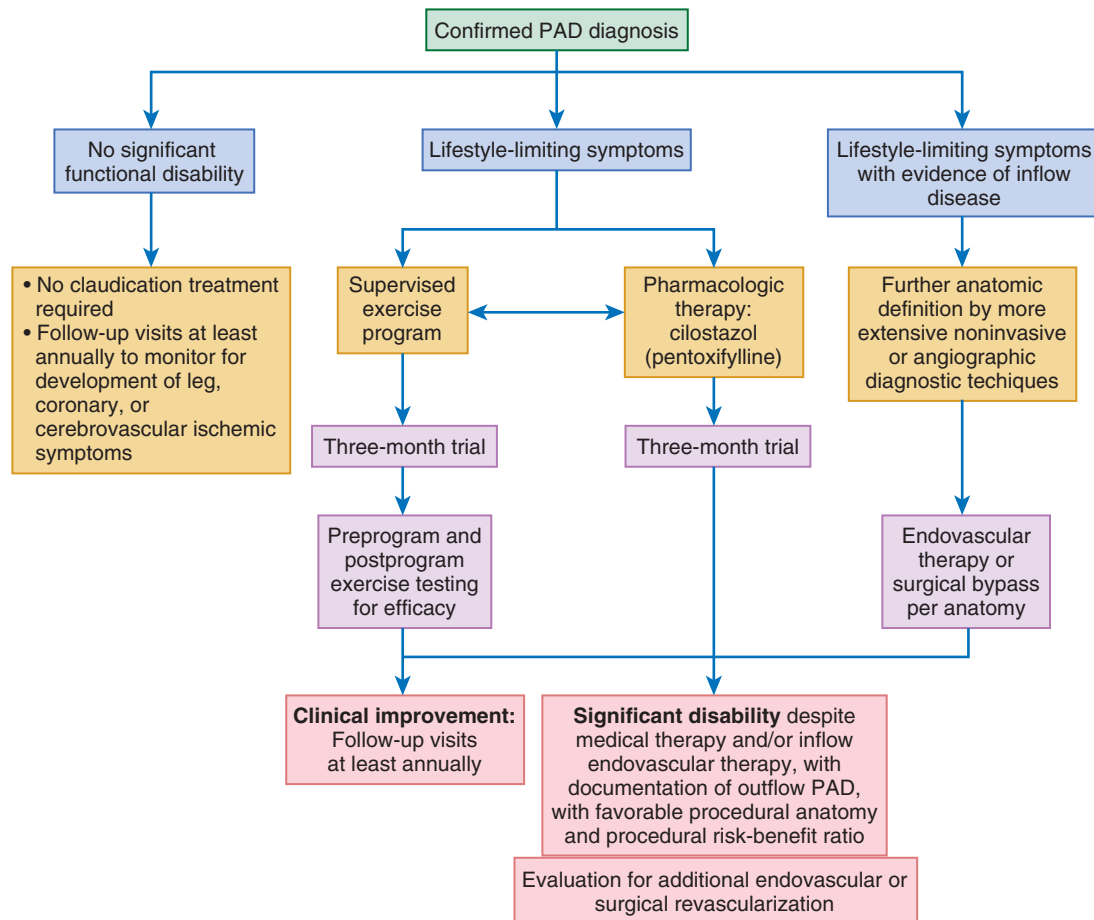

FIGURE 58-15 Management algorithm for the treatment of symptomatic PAD. (From Hirsch AT, Haskal ZJ, Hertzler NR, et al: ACC/AHA 2005 guidelines for the management of patients with peripheral arterial disease [lower extremity, renal, mesenteric, and abdominal aortic]: Executive summary a collaborative report from the American Association for Vascular Surgery/Society for Vascular Surgery, Society for Cardiovascular Angiography and Interventions, Society for Vascular Medicine and Biology, Society of Interventional Radiology, and the ACC/AHA Task Force on Practice Guidelines [Writing Committee to Develop Guidelines for the Management of Patients With Peripheral Arterial Disease] endorsed by the American Association of Cardiovascular and Pulmonary Rehabilitation; National Heart, Lung, and Blood Institute; Society for Vascular Nursing; TransAtlantic Inter-Society Consensus; and Vascular Disease Foundation. *J Am Coll Cardiol* 47:1239, 2006.)

counterparts in the legs, including the tibial, peroneal, plantar, and digital arteries. Involvement can extend to the cerebral, coronary, renal, mesenteric, aortoiliac, and pulmonary arteries.¹¹⁸ Pathologic findings include an occlusive, highly cellular thrombus that incorporates polymorphonuclear leukocytes, microabscesses, and occasionally multinucleated giant cells. The inflammatory infiltrate can also affect the vascular wall, but the internal elastic membrane remains intact. In the chronic phase of the disease, the thrombus becomes organized and the vascular wall becomes fibrotic.

The precise cause of TAO is not known. Tobacco use or exposure is present in virtually every patient. Hypercoagulability, immunologic mechanisms, and endothelial dysfunction may contribute to the pathogenesis of TAO. Potential immunologic mechanisms include increased cellular sensitivity to types I and III collagen and the presence of antiendothelial cell antibodies. CD4⁺ T cells have been identified in the cellular infiltrates of vessels of patients with TAO.^{118,119} The endothelial cells of affected arteries display increased expression of leukocyte adhesion molecules.¹¹⁹ Decreased endothelium-dependent vasodilation can occur in both the affected and unaffected limbs of patients with TAO. Some reports have found increased frequency of a prothrombin gene mutation, elevated plasma homocysteine concentration, or increased levels of anticardiolipin antibodies in patients with TAO.

Clinical Features

The prevalence of TAO is greater in Asia than in North America or western Europe. In the United States, TAO occurs in approximately 13 per 100,000 population.¹¹⁹ Symptoms develop in most patients before 45 years of age, and 75% to 90% are men. Patients can have claudication of the hands, forearms, feet, or calves. Most patients with TAO have pain at rest and digital ulcerations; frequently, more than one extremity is affected. The Raynaud phenomenon occurs in approximately 45% of patients, and superficial thrombophlebitis, which may be migratory, develops in approximately 40%. The risk for amputation within 5 years is approximately 25%.¹²⁰

The radial, ulnar, dorsalis pedis, and posterior tibial pulses may be absent. Two thirds of patients have abnormal Allen test results. To perform the Allen test, both the radial and ulnar arteries are compressed while the hand is clenched and then opened. This maneuver causes palmar blanching. Release of compression of either pulse should normally produce palmar erythema if the palmar arches are patent. If they are occluded, pallor persists on the side where compression is maintained. The distal aspects of the extremities may have discrete, tender, erythematous subcutaneous cords, indicative of superficial thrombophlebitis.

Diagnosis

No specific laboratory tests, other than biopsy, can diagnose TAO. Most tests therefore aim to exclude other diseases that might have similar clinical features, including autoimmune diseases such as scleroderma or systemic lupus erythematosus, hypercoagulable states, diabetes, and acute arterial occlusion secondary to embolism. Acute-phase indicators, such as the erythrocyte sedimentation rate or C-reactive protein, are usually normal. Serum immunologic markers, including antinuclear antibodies and rheumatoid factor, should not be present, and serum complement levels should be normal. If clinically indicated, a proximal source of embolism should be excluded by cardiac and vascular ultrasonography or by computed tomography, MRA, or conventional arteriography. Arteriography of an affected limb supports the diagnosis of TAO if there is segmental occlusion of small and medium arteries, absence of atherosclerosis, and corkscrew collateral vessels circumventing the occlusion (**Fig. 58-16**). These same findings, however, can occur in patients with scleroderma, systemic lupus erythematosus, mixed connective tissue disease, and antiphospholipid antibody syndrome. The conclusive test is a biopsy specimen showing the classic pathologic findings. This procedure is rarely indicated, however, and biopsy sites may fail to heal because of severe ischemia. The diagnosis therefore

FIGURE 58-16 Angiogram of a young woman with thromboangiitis obliterans. The **left panel** demonstrates occlusion of the anterior tibial and peroneal arteries (arrows). The **right panel** demonstrates an occlusion of the distal portion of the posterior tibial artery (arrow) with bridging collateral vessels.

usually depends on an age at onset of younger than 45 years, a history of tobacco use, physical examination demonstrating distal limb ischemia, exclusion of other diseases, and if necessary, angiographic demonstration of typical lesions.

Treatment

The cornerstone of treatment is cessation of tobacco use. Patients without gangrene who stop smoking rarely require amputation.^{119,120} In contrast, one or more amputations may ultimately be required in 40% to 45% of patients with TAO who continue to smoke.

No definitive drug therapy is available for limb ischemia in patients with TAO. Vascular reconstructive surgery is not usually a viable option because of the segmental nature of this disease and the involvement of distal vessels. An autogenous saphenous vein bypass graft can be considered if a target vessel for the distal anastomosis is available. Long-term patency rates are better in ex-smokers than in smokers.

TAKAYASU ARTERITIS AND GIANT CELL ARTERITIS

(See Chapter 84.)

FIBROMUSCULAR DYSPLASIA

Fibromuscular dysplasia affects medium and large arteries, typically the renal and carotid arteries. It also may involve the arteries supplying the leg, particularly the iliac arteries and less so the femoral, popliteal, tibial, and peroneal arteries.^{121,122} Fibromuscular dysplasia rarely causes either intermittent claudication or critical limb ischemia. It most often develops in young white women but can occur at any age in both sexes. Histopathologic examination shows fibroplasia most often affecting the media, but it can involve the intima or adventitia. The histologic classification of fibromuscular dysplasia includes the medial subtypes (medial fibroplasia, perimedial fibroplasia, and medial hyperplasia), as well as intimal fibroplasia and adventitial hyperplasia.¹²¹ Depending on the histopathologic type, stenosis results from hyperplasia of the fibrous or muscular components of the vessel wall. Angiography demonstrates a beaded appearance of arteries affected by medial and perimedial fibroplasia and

focal or tubular stenosis in arteries affected by intimal fibroplasia. Symptomatic patients can undergo percutaneous transluminal angioplasty.

POPLITEAL ARTERY ENTRAPMENT SYNDROME

Popliteal artery entrapment syndrome is an uncommon cause of intermittent claudication. It occurs when an anatomic variation in the configuration or insertion of the medial head of the gastrocnemius muscle compresses the popliteal artery.^{123,124} The popliteus muscle can also compress the popliteal artery and cause this syndrome. Popliteal artery entrapment is bilateral in approximately a third of affected patients. It should be suspected when a young, typically athletic, usually male person is evaluated for claudication. Potential consequences include popliteal artery thrombosis, embolism, and aneurysm formation.

Findings on peripheral pulse examination may be normal unless provocative maneuvers are performed. Walking or repeated ankle dorsiflexion and plantar flexion maneuvers may cause attenuation or disappearance of the pedal pulses and a decrease in the ABI in patients with popliteal artery entrapment. Imaging studies such as duplex ultrasonography, computed tomography, MRA, or conventional angiography, performed at rest and during ankle flexion maneuvers, can confirm the diagnosis. Magnetic resonance imaging and computed tomography will also provide information about the relationship of the gastrocnemius muscle to the popliteal artery.

Treatment of popliteal artery entrapment syndrome involves release of the popliteal artery, which may require division and reattachment of the medial head of the gastrocnemius muscle. On occasion, if the popliteal artery is occluded, surgical bypass is required.

ACUTE LIMB ISCHEMIA

Acute limb ischemia occurs when an arterial occlusion suddenly reduces blood flow to the arm or leg. The metabolic needs of the tissue outstrip perfusion, thereby placing limb viability in jeopardy. The clinical findings in patients with acute limb ischemia are related to the location of the arterial occlusion and the resulting decrease in blood flow. Depending on the severity of ischemia, patients may note disabling claudication or pain at rest. Pain may develop during a short period and affect the part of the extremity distal to the site of obstruction. It is not necessarily confined to the foot or toes or the hand or fingers, as is usually the case with chronic limb ischemia. Concurrent ischemia of peripheral nerves causes sensory loss and motor dysfunction. Findings on physical examination can include absence of pulses distal to the occlusion, cool skin, pallor, delayed capillary return and venous filling, diminished or absent sensory perception, and muscle weakness or paralysis. This constellation of symptoms and signs is often recalled as the six *p*'s: pain, paresthesias, pallor, pulselessness, poikilothermia, and paralysis.

Prognosis

Patients with acute limb ischemia usually have comorbid cardiovascular disorders, which may even be responsible for the ischemia. This population therefore has a poor long-term outcome. The 1-year survival rate is approximately 15% to 20% and is related to the comorbid conditions that predisposed the patient to acute limb ischemia.¹²⁵ Amputation is performed in 10% to 15% of patients during their initial hospitalization.¹²⁵ The risk for limb loss depends on the severity of the ischemia and the time elapsed before revascularization.

The Society for Vascular Surgery and the International Society for Cardiovascular Surgery developed a classification that takes into consideration the severity of ischemia and the viability of the limb, along with related neurologic findings and Doppler signals (**Table 58-6**).³¹

Pathogenesis

Causes of acute limb ischemia include arterial embolism, thrombosis in situ, dissection, and trauma. Most arterial emboli arise from thrombotic sources in the heart. Atrial fibrillation complicating valvular heart disease, congestive heart failure, CAD, and hypertension account for approximately 50% of cardiac emboli to the limbs. Other sources include rheumatic or prosthetic cardiac valves, ventricular thrombi resulting from MI or left ventricular aneurysm, paradoxical embolism of venous thrombi through intra-atrial or intraventricular communications, and cardiac tumors such as left atrial myxomas. Aneurysms of the aorta or peripheral arteries may harbor thrombi, which subsequently embolize to more distal arterial sites and usually lodge at branch points where the artery decreases in size.

Thrombosis in situ occurs in atherosclerotic peripheral arteries, infrainguinal bypass grafts, peripheral artery aneurysms, and normal arteries of patients with hypercoagulable states. In patients with peripheral atherosclerosis, thrombosis in situ may complicate plaque rupture and cause acute arterial occlusion and limb ischemia, as occurs in the coronary arteries of patients with acute MI. Thrombosis complicating popliteal artery aneurysms is a much more common complication than rupture and may account for 10% of cases of acute limb ischemia in elderly men.⁵ One of the most common causes of acute limb ischemia is thrombotic occlusion of an infrainguinal bypass graft, as discussed previously. Acute thrombotic occlusion of a normal artery is unusual but may occur in patients with acquired thrombophilic disorders such as antiphospholipid antibody syndrome, heparin-induced thrombocytopenia, disseminated intravascular coagulation, and myeloproliferative diseases. There is limited evidence that inherited thrombophilic disorders such as activated protein C resistance (factor V Leiden), prothrombin G20210 gene mutation, or deficiencies of antithrombin III and protein C and S increase the risk for acute peripheral arterial thrombosis.

Diagnostic Tests

The history and physical examination usually establish the diagnosis of acute limb ischemia. Tests should not delay urgent revascularization procedures to rescue a limb with threatened viability. Pressure in the affected limb and corresponding ABI can be measured if flow is detectable by Doppler ultrasonography. A Doppler probe

TABLE 58-6 Clinical Categories of Acute Limb Ischemia

CATEGORY	DESCRIPTION, PROGNOSIS	FINDINGS		DOPPLER SIGNALS	
		Sensory Loss	Muscle Weakness	Arterial	Venous
I. Viable	Not immediately threatened	None	None	Audible	Audible
II. Threatened					
a. Marginally	Salvageable if treated promptly	Minimal (toes) or none	None	(Often) inaudible	Audible
b. Immediately	Salvageable with immediate revascularization	More than toes, rest pain	Mild, moderate	(Usually) inaudible	Audible
III. Irreversible	Major tissue loss or permanent nerve damage inevitable	Profound, anesthetic	Profound, paralysis (rigor)	Inaudible	Inaudible

Modified from Rutherford RB, Baker JD, Ernst C, et al: Recommended standards for reports dealing with lower extremity ischemia: revised version. *J Vasc Surg* 26:517, 1997. Erratum in *J Vasc Surg* 2001 Apr;33:805.

can interrogate the presence of blood flow in peripheral arteries, particularly when pulses are not palpable. Color-assisted duplex ultrasonography can be used to determine the site of occlusion. It is particularly applicable for evaluation of the patency of infringuinal bypass grafts. Magnetic resonance imaging, computed tomography, and conventional contrast-enhanced arteriography can demonstrate the site of occlusion and provide an anatomic guide for revascularization.

Treatment

Analgesic medications should be administered to reduce pain. For patients with acute leg ischemia, the bed should be positioned such that the feet are lower than chest level, thereby increasing limb perfusion pressure by gravitational effects. Effort should be made to reduce pressure on the heels, on bone prominences, and between the toes by appropriate placement of soft material on the bed (such as sheepskin) and between the toes (such as lamb's wool). The room should be kept warm to prevent cold-induced cutaneous vasoconstriction.

Heparin should be administered intravenously immediately.¹²⁶ The dose should maintain the partial thromboplastin time at 2.0 to 2.5 times control values to prevent propagation of thrombi or recurrent embolism. It is not known whether low-molecular-weight heparin is as effective as unfractionated heparin in patients with acute limb ischemia.

Revascularization is indicated when the viability of the limb is threatened or when symptoms of ischemia persist. Options for restoration of blood flow include endovascular revascularization via intra-arterial thrombolytic therapy, percutaneous mechanical thrombectomy, and surgical revascularization. Catheter-directed intra-arterial thrombolysis plus thrombectomy is an initial treatment option for patients with either category I or II acute limb ischemia if

they have no contraindication to thrombolysis.¹²⁶ Catheter-based thrombolysis can also be considered for patients at high risk for surgical intervention. Identification and repair of a graft stenosis after successful thrombolysis improve long-term graft patency.¹²⁵ The thrombolytic regimens currently used include the recombinant tissue plasminogen activators alteplase, reteplase, and tenecteplase. Catheter-based thrombolytic therapy should generally be continued for 24 to 48 hours to achieve optimal benefit and to limit the risk for bleeding. Adjuvant use of platelet glycoprotein IIb/IIIa inhibitors shortens thrombolysis time but does not improve outcome.¹²⁵ Percutaneous, catheter-based mechanical thrombectomy, with devices that remove thrombus via aspiration, rheolysis, fragmentation, or high-energy ultrasound, can be used alone or in addition to pharmacologic thrombolysis to treat patients with acute limb ischemia.¹²⁶ Surgical revascularization, including thromboembolectomy and bypass of the occluded area, is an option for restoration of blood flow to an ischemic limb. Hybrid approaches combining surgical and endovascular techniques may be used for complex cases. Five prospective randomized trials have compared the benefits and risks of thrombolysis and surgical reconstruction in patients with acute limb ischemia.¹²⁵ Overall, no difference was seen in the rate of death or amputation during the 1 year between the two interventions, although patients undergoing thrombolysis had a greater risk for major bleeding within 30 days. Findings from the individual trials suggest that catheter-based thrombolysis is an appropriate initial option in patients with viable or marginally threatened limbs and when the ischemia is of less than 14 days' duration, whereas surgical revascularization is more appropriate in those with immediately threatened limbs and in those whose symptoms have lasted for more than 14 days. Patients with irreversible injury require amputation (Fig. 58-17).

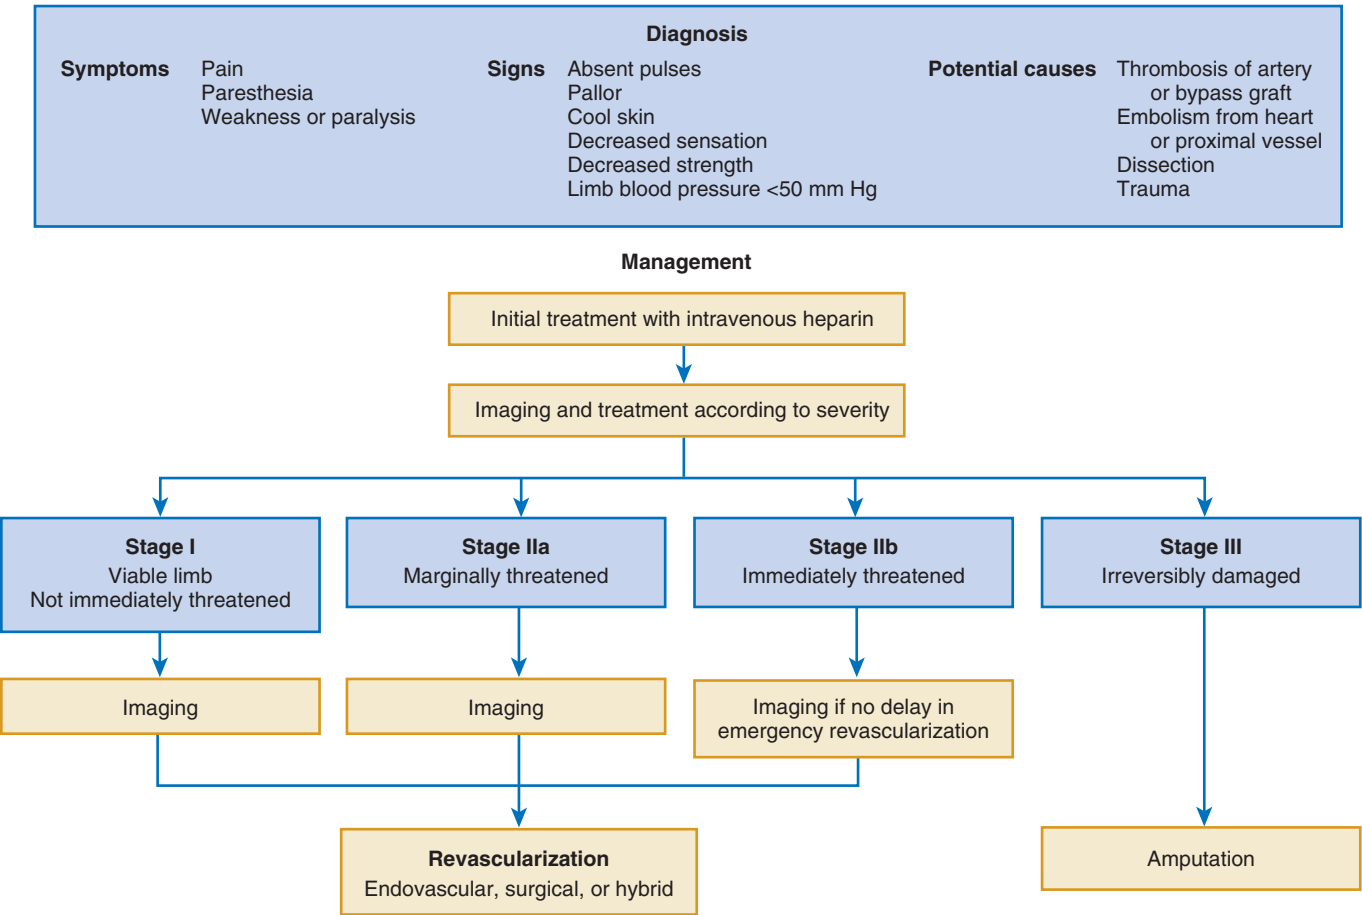

FIGURE 58-17 Algorithm for the diagnosis and treatment of acute limb ischemia. (From Creager MA, Kaufman JA, Conte MS: Clinical practice. Acute limb ischemia. N Engl J Med 366:2198, 2012.)

ATHEROEMBOLISM

Atheroembolism refers to occlusion of arteries resulting from detachment and embolization of atheromatous debris, including fibrin, platelets, cholesterol crystals, and calcium fragments. Other terms include atherogenic embolism and cholesterol embolism. Atheroemboli originate most frequently from shaggy protruding atheroma of the aorta and less frequently from atherosclerotic branch arteries. The atheroemboli typically occlude small downstream arteries and arterioles of the skin, extremities, brain, eyes, kidneys, or mesentery.¹²⁷ Most affected individuals are men older than 60 years with clinical evidence of atherosclerosis.

Pathogenesis

Patients with aortic atherosclerosis characterized by large complex atheromas have the greatest risk for atheroembolism¹²⁸ (**Fig. 58-18**). Identification of large protruding atheromas by transesophageal ultrasound predicts future embolic events.¹²⁹ Atheroemboli typically occlude arterioles and small arteries. Approximately 50% of atheroemboli involve vessels in the lower extremities. Catheter manipulation causes a large proportion of atheroemboli, which develop in approximately 1% to 2% of patients undergoing endovascular procedures.^{127,128} Similarly, surgical manipulation of the aorta during cardiac or vascular operations may precipitate atheroembolism. Controversy remains whether anticoagulants or thrombolytic drugs contribute to atheroembolism.¹²⁹ Recent clinical trials of anticoagulant drugs have found a relatively low incidence of atheroembolism in patients with large aortic plaques.¹²⁷

Clinical Features

The most notable clinical features of atheroembolism involving the extremities include painful cyanotic toes, a condition called blue toe syndrome (**Fig. 58-19**). Livedo reticularis occurs in approximately 50% of patients. Local areas of erythematous or violaceous discoloration may be present on the lateral aspects of the feet and the soles, as well as on the calves. Other findings include digital and foot ulcerations, nodules, purpura, and petechiae. Pedal pulses are typically present

because the emboli tend to lodge in the more distal digital arteries and arterioles. Symptoms and signs indicating additional organ involvement with atheroemboli should be sought. Funduscopy can be used to visualize Hollenhorst plaques in patients with visual loss secondary to retinal ischemia or infarction. Renal involvement, manifested by increased blood pressure and azotemia, commonly occurs in patients with peripheral atheroemboli. Patients also sometimes show evidence of mesenteric or bladder ischemia and splenic infarction.

The clinical setting and findings usually suffice for the diagnosis of atheroembolism, but other diseases may have some of the manifestations of atheroemboli. As discussed previously, critical limb ischemia occurs in patients with severe peripheral atherosclerosis, and acute limb ischemia results from thromboembolism, both conditions that would have abnormal findings on pulse examination. Hypersensitivity vasculitides secondary to connective tissue diseases, infections, drugs, polyarteritis nodosa, or cryoglobulinemia generally involve multiple organ systems and cause cutaneous findings of purpura, ulcers, and digital ischemia, similar to those resulting from atheroemboli (**see Chapter 84**). Procoagulant disorders such as antiphospholipid antibody syndrome, heparin-induced thrombocytopenia, and myeloproliferative disorders such as essential thrombocythemia can cause digital artery thrombosis with resultant digital ischemia, cyanosis, and ulceration.

Diagnostic Tests

Laboratory findings consistent with atheroembolism include an elevated erythrocyte sedimentation rate, eosinophilia, and eosinophiluria. Other findings may include anemia, thrombocytopenia, hypocomplementemia, and azotemia. Imaging of the aorta with transesophageal ultrasound, MRA, or computed tomography may identify sites of severe atherosclerosis and shaggy atheroma indicating a source of the atheroemboli. The only definitive test for atheroembolism is pathologic confirmation on skin or muscle biopsy specimens. Pathognomonic findings include elongated needle-shaped clefts in small arteries caused by cholesterol crystals and often accompanied by inflammatory infiltrates composed of lymphocytes and possibly giant cells and eosinophils, intimal thickening, and perivascular fibrosis.

FIGURE 58-18 Atherosclerotic aorta of a patient with atheroemboli. Multiple, protruding, shaggy atheromas with superimposed mural thrombi are present. (Courtesy R. N. Mitchell, MD, PhD, Department of Pathology, Brigham and Women's Hospital, Boston.)

FIGURE 58-19 Atheroemboli involving the foot or "blue toe syndrome." There is cyanotic discoloration of the toes along with localized areas of violaceous discoloration. (Modified from Beckman JA, Creager MA: *Peripheral artery disease: Clinical evaluation*. In Creager MA, Beckman JA, Loscalzo J [eds]: *Vascular Medicine: A Companion to Braunwald's Heart Disease*. 2nd ed. Philadelphia, Elsevier, 2013, p 231.)

Treatment

No definitive treatment has been established for atheroembolism. Analgesics should be administered for pain. Local foot care should be provided as described previously for patients with acute limb ischemia. It may be necessary to excise or amputate necrotic areas.

Patients with this condition are at risk for recurrent atheroembolic events. Risk factor modification, such as lipid-lowering therapy with statins and smoking cessation, can favorably affect the overall outcome of atherosclerosis, but whether such intervention will prevent recurrent atheroembolism is unknown. The use of antiplatelet drugs to prevent recurrent atheroembolism remains controversial. It is reasonable, however, to administer antiplatelet agents, even in the absence of strong clinical evidence of efficacy, because the agents may prevent other adverse cardiovascular events in patients with atherosclerosis. The use of warfarin also engenders controversy, and some investigators have even suggested that anticoagulants precipitate atheroemboli, whereas others have found that warfarin reduces atheroembolic events, particularly in patients with mobile aortic atheroma.¹²⁸ The use of corticosteroids to treat atheroembolism is also controversial.

Surgical removal of the source should be considered in patients with atheroembolism, particularly in those with recurrence. Surgical procedures include excision and replacement of affected portions of the aorta, endarterectomy, and bypass operations. Operative intervention targets the site of the aorta and iliac or femoral arteries where aneurysm formation or mobile atherosclerotic plaque is evident. Frequently, diffuse aortic disease makes it difficult to identify the precise segment responsible for the atheroembolism. In addition, many of these patients are elderly and have coexisting CAD, which increases the risk associated with major vascular operations. Several small case series have reported endovascular placement of stents and stent grafts to prevent recurrent atheroembolism.^{127,128}

GUIDELINES

Peripheral Artery Diseases

Mark A. Creager and Peter Libby

The American College of Cardiology Foundation/American Heart Association (ACCF/AHA) Task Force on Practice Guidelines published guidelines for the management of patients with peripheral artery disease (PAD) in 2005,¹ updated them in 2011,² and integrated them into a single compilation in 2013.³ This summary presents salient features and important recommendations from these guidelines. We omit some recommendations superseded by more recent statements or data.

VASCULAR HISTORY AND PHYSICAL EXAMINATION

The ACCF/AHA guidelines state that practitioners should query patients at risk for PAD about limitations in walking caused by symptoms of fatigue, aching, numbness, or pain in the buttocks, thighs, calves, or feet and about leg discomfort associated with exertion and rest. Additional questions can determine whether the patient has pain even at rest or poorly healing or nonhealing wounds of the legs or feet. The guidelines recommend performance of a comprehensive pulse examination and careful inspection of the feet. This includes measurement of blood pressure in both arms; auscultation of the carotid arteries, abdomen, and femoral arteries for bruits; and palpation of the brachial, radial, ulnar, femoral, popliteal, dorsalis pedis, and posterior tibial artery pulses. The feet are inspected to assess skin color, temperature, integrity, and the presence of ulcerations (Table 58G-1).

DIAGNOSTIC TESTS

Noninvasive vascular diagnostic techniques provide adjunctive diagnostic information to the history and physical examination. Such tests

TABLE 58G-1 ACCF/AHA Guidelines: Vascular History and Physical Examination of Patients with Peripheral Artery Disease

CLASS	INDICATION	LEVEL OF EVIDENCE
I	1. Individuals at risk for lower extremity PAD should undergo a vascular review of symptoms to assess walking impairment, claudication, ischemic rest pain, and/or the presence of nonhealing wounds.	C
	2. Individuals at risk for lower extremity PAD should undergo comprehensive pulse examination and inspection of the feet.	C

127. Shepherd RFJ: Atheroembolism. *In* Creager MA, Beckman JA, Loscalzo J, (eds): *Vascular Medicine: A Companion to Braunwald's Heart Disease*. 2nd ed. Philadelphia, Elsevier, 2013, pp 572–586.

include physiologic measurements and imaging studies. Noninvasive physiologic assessment may include the ankle-brachial and toe-brachial indices, segmental pressure measurements, Doppler waveform analysis, pulse volume recordings, and exercise testing (Table 58G-2; see Chapter 58).

MEDICAL MANAGEMENT OF PATIENTS WITH PERIPHERAL ARTERY DISEASE

Medical treatment of patients with PAD is directed toward reducing adverse cardiovascular events and improving symptoms of intermittent claudication. Drugs, other risk factor-modifying measures, and antiplatelet agents can decrease the risk for myocardial infarction (MI), stroke, and cardiovascular death. Supervised exercise training and cilostazol improve walking distance in patients with claudication (Table 58G-3). Medical therapies have not been demonstrated to preserve limb viability in patients with critical limb ischemia, and these patients should undergo urgent evaluation for revascularization.

REVASCULARIZATION STRATEGIES FOR PATIENTS WITH PERIPHERAL ARTERY DISEASE

Revascularization procedures can improve symptoms and preserve limb viability. These procedures are broadly categorized as endovascular interventions and surgical reconstruction, although hybrid procedures consisting of both endovascular and surgical revascularization are also used. In determining the type of revascularization procedure, one important consideration is the location of the obstruction, which is broadly categorized as inflow, involving the aorta and iliac arteries; outflow, including the femoral and popliteal arteries; or run-off, affecting the tibial and peroneal arteries. The decision to perform endovascular or surgical procedures also depends on the clinical context and the morphologic features and distribution of the stenotic and occlusive lesions. The TransAtlantic Inter-Society Consensus (TASC) Working Group has developed a grading system that characterizes stenotic lesions.⁴ Endovascular interventions may involve percutaneous transluminal angioplasty (PTA) with balloon dilation, stents, atherectomy, and thrombolysis. Surgical procedures include aortobifemoral bypass; iliac endarterectomy; extra-anatomic bypass, such as femoral-femoral and axillobifemoral bypass; and infrainguinal bypass procedures, such as femoral-popliteal and femoral-tibial bypass. Infrainguinal bypass procedures generally use saphenous veins for the bypass conduit, but other veins or synthetic material may also be used, such as polytetrafluoroethylene (PTFE) (Table 58G-4).

MANAGEMENT OF ACUTE LIMB ISCHEMIA

The ACCF/AHA guidelines state that patients with symptoms and signs of acute limb ischemia should undergo emergency evaluation and treatment to preserve viability in a salvageable extremity. Revascularization strategies include catheter-based thrombolysis/

TABLE 58G-2 ACCF/AHA Guidelines for Diagnostic Testing of Patients with Peripheral Artery Disease

CLASS	INDICATION	LEVEL OF EVIDENCE
I	1. The resting ankle-brachial index (ABI) should be used to establish the diagnosis of lower extremity PAD in patients with suspected lower extremity PAD, defined as individuals with one or more of the following: exertional leg symptoms, nonhealing wounds, 65 years of age and older, or 50 years of age and older with a history of smoking or diabetes.	B
	2. The toe-brachial index should be used to establish the diagnosis of lower extremity PAD in patients in whom lower extremity PAD is clinically suspected but in whom the ABI test is not reliable because of noncompressible vessels.	B
	3. Leg segmental pressure measurements are useful in establishing the diagnosis of lower extremity PAD when anatomic localization of lower extremity PAD is required to create a therapeutic plan.	B
	4. ABI results should be reported uniformly, with noncompressible values defined as >1.40 , normal values as $1.00-1.40$, borderline values as $0.91-0.99$, and abnormal values as ≤ 0.90 .	B
	5. Continuous-wave Doppler ultrasound blood flow measurements can provide an accurate assessment of the location and severity of lower extremity PAD, monitor the progression of lower extremity PAD, and provide quantitative follow-up after revascularization procedures.	B
	6. Exercise treadmill tests with measurement of preexercise and postexercise ABI values are recommended to provide diagnostic data useful in differentiating arterial claudication from nonarterial claudication ("pseudoclaudication").	B
	7. Duplex ultrasound of the extremities is useful for diagnosing the anatomic location and degree of stenosis in PAD.	A
	8. Magnetic resonance angiography (MRA) of the extremities is useful for diagnosing the anatomic location and degree of stenosis in PAD.	A
	9. MRA of the extremities is useful in selecting patients with lower extremity PAD as candidates for endovascular intervention.	A
	10. Contrast-enhanced angiography provides detailed information about arterial anatomy and is recommended for evaluating patients with lower extremity PAD when revascularization is contemplated.	B
IIa	1. Pulse volume recordings are reasonable to establish the initial diagnosis of lower extremity PAD, assess its location and severity, and monitor the status of lower extremity revascularization procedures.	B
	2. Noninvasive imaging modalities, including MRA, computed tomographic angiography (CTA), and color flow duplex imaging, may be used in advance of invasive imaging to develop an individualized diagnostic strategic plan, including assistance in selection of access sites, identification of significant lesions, and determination of the need for invasive evaluation.	B
IIb	1. CTA of the extremities may be considered for diagnosis of the anatomic location and presence of significant stenosis in patients with lower extremity PAD.	B
	2. CTA of the extremities may be considered as a substitute for MRA in patients with contraindications to MRA.	B
	3. MRA of the extremities may be considered to select patients with lower extremity PAD as candidates for surgical bypass and to select the sites of surgical anastomosis.	B

TABLE 58G-3 ACCF/AHA Guidelines for Medical Management of Patients with Peripheral Artery Disease

CLASS	INDICATION	LEVEL OF EVIDENCE
I	1. Treatment with a hydroxymethylglutaryl-coenzyme A reductase inhibitor (statin) medication is indicated for all patients with PAD to achieve a target low-density lipoprotein (LDL) cholesterol level of <100 mg/dL.	B
	2. Antihypertensive therapy should be administered to hypertensive patients with lower extremity PAD to achieve a goal of <140 mm Hg systolic over 90 mm Hg diastolic (individuals without diabetes) or <130 mm Hg systolic over 80 mm Hg diastolic (individuals with diabetes and those with chronic renal disease) to reduce the risk for MI, stroke, congestive heart failure, and cardiovascular death.	A
	3. Patients who smoke cigarettes should be assisted by counseling and developing a plan for quitting that may include pharmacotherapy and/or referral to a smoking cessation program.	A
	4. In the absence of contraindications or other compelling clinical indications, one or more of the following pharmacologic therapies should be offered: varenicline, bupropion, and nicotine replacement therapy.	A
	5. Antiplatelet therapy is indicated to reduce the risk for MI, stroke, and vascular death in individuals with symptomatic atherosclerotic lower extremity PAD, including those with intermittent claudication or critical limb ischemia (CLI), previous lower extremity revascularization (endovascular or surgical), or previous amputation for lower extremity ischemia.	A
	6. Proper foot care, including the use of appropriate footwear, chiropody/podiatric medicine, daily foot inspection, skin cleansing, and topical moisturizing creams, should be encouraged, and skin lesions and ulcerations should be addressed urgently in all patients with diabetes and lower extremity PAD.	B
	7. A program of supervised exercise training is recommended as an initial treatment modality for patients with intermittent claudication.	A
	8. Cilostazol (100 mg orally 2 times per day) is indicated as an effective therapy to improve symptoms and increase walking distance in patients with lower extremity PAD and intermittent claudication (in the absence of heart failure).	A
IIa	1. Treatment with a statin medication to achieve a target LDL cholesterol level of <70 mg/dL is reasonable for patients with lower extremity PAD at very high risk for ischemic events.	B
	2. The use of angiotensin-converting enzyme (ACE) inhibitors is reasonable for symptomatic patients with lower extremity PAD to reduce the risk for adverse cardiovascular events.	B
	3. Treatment of diabetes in individuals with lower extremity PAD by administration of glucose control therapies to reduce hemoglobin A1c to $<7\%$ can effectively reduce microvascular complications and potentially improve cardiovascular outcomes.	C
	4. Antiplatelet therapy can reduce the risk for MI, stroke, or vascular death in asymptomatic individuals with an ABI of ≤ 0.90 .	C

Continued

TABLE 58G-3 ACCF/AHA Guidelines for Medical Management of Patients with Peripheral Artery Disease—cont'd

CLASS	INDICATION	LEVEL OF EVIDENCE
IIb	1. ACE inhibitors may be considered for patients with asymptomatic lower extremity PAD to reduce the risk for adverse cardiovascular events.	C
	2. The usefulness of antiplatelet therapy to reduce the risk for MI, stroke, or vascular death in asymptomatic individuals with a borderline abnormal ABI, defined as 0.91-0.99, is not well established.	A
	3. The combination of aspirin and clopidogrel may be considered to reduce the risk for cardiovascular events in patients with symptomatic atherosclerotic lower extremity PAD, including those with intermittent claudication or CLI, previous lower extremity revascularization (endovascular or surgical), or previous amputation for lower extremity ischemia, who do not have an increased risk for bleeding and who have a high perceived cardiovascular risk.	B
	4. The usefulness of unsupervised exercise programs is not well established as an effective initial treatment modality for patients with intermittent claudication.	B
	5. Pentoxifylline (400 mg 3 times per day) may be considered as a second-line alternative therapy to cilostazol to improve walking distance in patients with intermittent claudication.	A
	6. Parenteral administration of prostaglandin E ₁ or iloprost for 7-28 days may be considered to reduce ischemic pain and facilitate ulcer healing in patients with CLI, but its efficacy is likely to be limited to a small percentage of patients.	A
III	1. In the absence of any other proven indication for warfarin, its addition to antiplatelet therapy to reduce the risk for adverse cardiovascular ischemic events in individuals with atherosclerotic lower extremity PAD has no benefit and is potentially harmful because of an increased risk for major bleeding.	B
	2. Oral vasodilator prostaglandins such as beraprost and iloprost are not effective medications to improve walking distance in patients with intermittent claudication.	A
	3. Vitamin E is not recommended for the treatment of patients with intermittent claudication.	C
	4. Chelation (e.g., ethylenediaminetetraacetic acid) is not indicated for the treatment of intermittent claudication and may have harmful adverse effects.	A
	5. Parenteral administration of pentoxifylline is not useful for the treatment of CLI.	B
	6. Oral iloprost is not an effective therapy to reduce the risk for amputation or death in patients with CLI.	B

TABLE 58G-4 ACCF/AHA Guidelines for Revascularization of Patients with Peripheral Artery Disease

CLASS	INDICATION	LEVEL OF EVIDENCE
I	1. Endovascular procedures are indicated for individuals with a vocational- or lifestyle-limiting disability because of intermittent claudication when the clinical features suggest a reasonable likelihood of symptomatic improvement with endovascular intervention and (1) the response to exercise or pharmacologic therapy has been inadequate and/or (2) the risk-to-benefit ratio is very favorable (e.g., focal aortoiliac occlusive disease).	A
	2. Stenting is effective as primary therapy for common iliac artery stenosis and occlusions.	B
	3. Stenting is effective as primary therapy for external iliac artery stenosis and occlusions.	C
	4. Endovascular intervention is recommended as the preferred revascularization technique for TASC type A iliac and femoropopliteal arterial lesions.	B
	5. Surgical interventions are indicated for individuals with claudication symptoms who have a significant functional disability that is vocation or lifestyle limiting, who are unresponsive to exercise or pharmacotherapy, and who have a reasonable likelihood of symptomatic improvement.	B
	6. Aortobifemoral bypass is beneficial for patients with vocation- or lifestyle-disabling symptoms and hemodynamically significant aortoiliac disease who are acceptable surgical candidates and are unresponsive to or unsuitable for exercise, pharmacotherapy, or endovascular repair.	B
	7. Bypasses to the popliteal artery above the knee should be constructed with an autogenous vein when possible.	A
	8. Bypasses to the popliteal artery below the knee should be constructed with an autogenous vein when possible.	B
	9. Patients who have significant necrosis of the weight-bearing portions of the foot (in ambulatory patients), an uncorrectable flexion contracture, paresis of the extremity, refractory ischemic rest pain, sepsis, or a very limited life expectancy because of comorbid conditions should be evaluated for primary amputation of the leg.	C
IIa	1. Stents (and other adjunctive techniques such as lasers, cutting balloons, atherectomy devices, and thermal devices) can be useful in the femoral, popliteal, and tibial arteries as salvage therapy for a suboptimal or failed result from balloon dilation (e.g., persistent translesional gradient, residual diameter stenosis >50%, or flow-limiting dissection).	C
	2. The use of synthetic grafts to the popliteal artery below the knee is reasonable only when no autogenous vein from the ipsilateral or contralateral leg or arms is available.	A
	3. For patients with limb-threatening lower extremity ischemia and an estimated life expectancy of ≤2 years in whom an autogenous vein conduit is not available, balloon angioplasty is reasonable to perform when possible as the initial procedure to improve distal blood flow.	B
	4. For patients with limb-threatening ischemia and an estimated life expectancy of >2 years, bypass surgery, when possible and when an autogenous vein conduit is available, is reasonable to perform as the initial treatment to improve distal blood flow.	B

TABLE 58G-4 ACCF/AHA Guidelines for Revascularization of Patients with Peripheral Artery Disease—cont'd

CLASS	INDICATION	LEVEL OF EVIDENCE
IIb	1. The effectiveness of stents, atherectomy, cutting balloons, thermal devices, and lasers for the treatment of femoral-popliteal arterial lesions (except to salvage a suboptimal result from balloon dilation) is not well established.	A
	2. The effectiveness of uncoated/uncovered stents, atherectomy, cutting balloons, thermal devices, and lasers for the treatment of infrapopliteal lesions (except to salvage a suboptimal result from balloon dilation) is not well established.	C
	3. Because the presence of more aggressive atherosclerotic occlusive disease is associated with less durable results in patients younger than 50 years, the effectiveness of surgical intervention for intermittent claudication in this population is unclear.	B
III	1. Endovascular intervention is not indicated if no significant pressure gradient across a stenosis occurs despite flow augmentation with vasodilators.	C
	2. Endovascular intervention is not indicated as prophylactic therapy in asymptomatic patients with lower extremity PAD.	C
	3. Surgical intervention is not indicated to prevent progression to limb-threatening ischemia in patients with intermittent claudication.	B
	4. Surgical and endovascular intervention is not indicated in patients with severe decrements in limb perfusion (e.g., ankle-brachial index <0.4) in the absence of clinical symptoms of critical limb ischemia.	C

TABLE 58G-5 ACCF/AHA Guidelines for Management of Acute Limb Ischemia

CLASS	INDICATION	LEVEL OF EVIDENCE
I	1. Patients with acute limb ischemia and a salvageable extremity should undergo an emergency evaluation that defines the anatomic level of occlusion and leads to prompt endovascular or surgical revascularization.	B
	2. Catheter-based thrombolysis is an effective and beneficial therapy and is indicated for patients with acute limb ischemia (Rutherford categories I and IIa) of <14 days' duration.	A
IIa	1. Mechanical thrombectomy devices can be used as adjunctive therapy for acute limb ischemia secondary to peripheral arterial occlusion.	B
IIb	1. Catheter-based thrombolysis or thrombectomy may be considered for patients with acute limb ischemia (Rutherford category IIb) of >14 days' duration.	B
III	1. Patients with acute limb ischemia and a nonviable extremity should not undergo an evaluation to define the vascular anatomy or efforts to attempt revascularization.	B

thrombectomy or surgical revascularization. Considerations for determining the type of revascularization procedure used to treat acute limb ischemia include the cause of acute arterial occlusion, the duration of time since the onset of symptoms, and the severity of limb ischemia (**Table 58G-5**).

REFERENCES, 1346

Each year, more than 795,000 Americans have strokes and more than 150,000 die, thus making stroke the country's fourth leading cause of death.¹ More than 25% of stroke survivors older than 65 years of age are institutionalized in a nursing home 6 months later.¹ Stroke disproportionately affects minority populations. More than 60% of stroke-related deaths occur in women, and women are less than half as likely as men to be able to live independently after stroke.¹ Although age is a major risk factor for stroke, more than a third of strokes occur in persons younger than 65 years of age.¹ Risk factors for stroke overlap with those for coronary and peripheral artery disease, yet stroke can reflect a diverse set of pathophysiologic processes, and therapeutic interventions can confer levels of benefit and risk that differ from those for other forms of vascular disease.² This discussion focuses on therapeutic interventions for prevention and treatment of stroke that are of particular relevance to cardiologists. The American Heart Association/American Stroke Association (AHA/ASA) has provided detailed, current evidence-based guidelines for prevention of a first stroke,² prevention of recurrent stroke,³ and emergency management of patients with ischemic stroke.⁴

This chapter reviews various aspects of medical therapy for ischemic stroke. Readers are directed to AHA guidelines reviewing the use of carotid endarterectomy and angioplasty/stenting for primary and secondary prevention of stroke and to [Chapter 60](#).⁵ COSS (Carotid Occlusion Surgery Study) found no benefit of extracranial-intracranial arterial bypass surgery over medical therapy in patients with symptomatic atherosclerotic internal carotid artery occlusion and hemodynamic cerebral ischemia (primary endpoint, stroke and death from surgery through 30 days and ipsilateral ischemic stroke within 2 years of randomization): 21.0% (95% confidence interval [CI], 12.8% to 29.2%) for the surgical group and 22.7% (95% CI, 13.9% to 31.6%) for the medical group ($P = 0.78$).⁶

MEDICAL THERAPY FOR PREVENTION OF STROKE

Approximately 78% of strokes are first events, which makes primary prevention of paramount importance.¹ Prevention of recurrent events is also critical. Depending on age and race or ethnicity, between approximately 6% and 25% of survivors will have a second stroke within 5 years.¹ The risk for ischemic stroke after a transient ischemic attack (TIA, a frequently misdiagnosed condition, is defined as "a transient episode of neurological dysfunction caused by focal brain, spinal cord, or retinal ischemia, without acute infarction") is as high as 17% over a 90-day period (with the highest risk in the first week).⁷ The ABCD² score can be helpful in assessing the short-term risk for stroke in patients with TIA ([Table 59-1](#)).⁸ The risk for stroke within 2 days is low (1%) in those with a score of 0 to 3, moderate (4%) in those with a score of 4 to 5, and high (8%) in those with a score of 6 to 7.⁸ Several studies suggest that patients with a low ABCD² score can be

evaluated rapidly and managed in an outpatient, specialized clinic or a similar unit, but even those at apparent low risk may have a condition requiring urgent treatment.⁹ The risks and benefits of therapeutic interventions differ for primary and secondary prevention of stroke.

Platelet Antiaggregants Primary Prevention

The use of platelet antiaggregants for primary prevention of stroke depends on the patient's global risk for cardiovascular events and stroke. No evidence has shown that platelet antiaggregants reduce the risk for stroke in persons at low risk.²

The benefit of aspirin for primary cardiovascular prophylaxis outweighs its associated risk for bleeding complications in persons with a 10-year risk for coronary heart events of 6% to 10%, but there is no evidence of a reduction in risk for stroke even in these patients (predominately men), and aspirin is not recommended for this purpose.⁸ Although the Women's Health Study found no reduction in its pre-specified primary endpoint (nonfatal myocardial infarction [MI], nonfatal stroke, or cardiovascular death) with aspirin (100 mg on alternate days), there was a 17% reduction in the risk for stroke, albeit with an increase in the risk for bleeding.¹⁰ This benefit occurred primarily in women at increased risk for stroke because of the presence of other factors (e.g., hypertension, diabetes). Thus aspirin may be considered in women whose risk for stroke outweighs its associated bleeding risk.⁸ There is no evidence of benefit in reducing the risk for a first stroke with any other platelet antiaggregant.

Anticoagulation is generally recommended for prevention of stroke in patients with atrial fibrillation who have a high risk for systemic embolization.³ In addition to warfarin, new agents have become available for prevention of a first and recurrent stroke in patients with nonvalvular atrial fibrillation ([see later and Chapters 38 and 82](#)).³ Aspirin plus clopidogrel may decrease the risk for major vascular events (MVEs, predominately stroke) and stroke ([Fig. 59-1](#)) in comparison to aspirin alone in patients with atrial fibrillation who cannot take anticoagulants, but the combination is associated with an increased risk for major bleeding complications such that no overall net benefit was achieved (MVEs decreased 0.8% per year, major hemorrhages increased 0.7% per year; relative risk [RR], 0.97; 95% CI, 0.89 to 1.06; $P = 0.54$).¹¹ Apixaban may be superior to aspirin in preventing stroke or systemic embolization, and has a similar rate of major bleeding ([Fig. 59-2](#)).^{3,12}

Secondary Prevention

Aspirin (lowest efficacious dose in comparison to placebo, 50 mg/day) lowers the risk for recurrent stroke by approximately 15% in persons with noncardioembolic ischemic stroke.⁷ Sustained-release dipyridamole (200 mg twice daily) is as efficacious as aspirin in reducing the risk for recurrent stroke, with a further reduction ($\approx 37\%$)

(From ACTIVE Investigators: Effect of clopidogrel added to aspirin in patients with atrial fibrillation. *N Engl J Med* 360:2066, 2009.)

when the two drugs are combined.^{7,13} Aspirin plus sustained-release dipyridamole is available in the United States in a fixed-dose combination (25 mg aspirin plus 200 mg dipyridamole) that is given twice daily. Cardiologists are often concerned that dipyridamole might increase the risk for cardiac ischemia, but clinical trials have not substantiated this reservation. There is also concern that the total dose of aspirin (50 mg/day), although efficacious for secondary stroke prophylaxis, is below the dose shown to be effective for cardiac prophylaxis. To address this potential limitation, a small additional dose of aspirin can be added (e.g., 81 mg/day) to the fixed combination of aspirin and dipyridamole.¹³

Clopidogrel monotherapy given to patients with a history of MI, stroke, or symptomatic peripheral arterial disease reduces the combined risk for MI, stroke, or vascular death by 8.7% as compared with aspirin.⁷ Although based on a potentially underpowered subgroup analysis, there is no evidence of a significant reduction in stroke in those with previous stroke.⁷ No reduction in a composite endpoint of MI, stroke, or cardiovascular death in patients with cardiovascular disease (including stroke) or multiple risk factors was found with aspirin plus clopidogrel versus aspirin alone.¹⁴ When tested directly in patients with stroke, the combination of aspirin and clopidogrel was associated with an increase in bleeding complications without a reduction in ischemic stroke.¹⁵ SP3 (Stroke Prevention Study 3) similarly found a higher risk for hemorrhage with no reduction in ischemic events after lacunar stroke in those treated with the

combination versus aspirin alone (Fig. 59-3).¹⁶ Aspirin and clopidogrel should not be used in combination for stroke prophylaxis in patients at high risk or in patients with recent stroke.⁷

A direct comparison found that aspirin plus dipyridamole was comparable to clopidogrel monotherapy for secondary stroke prevention in patients with noncardioembolic stroke (Fig. 59-4).¹⁷ Aspirin, aspirin plus sustained-release dipyridamole, and clopidogrel are reasonable options for secondary prevention in these types of patients.⁷

**Anticoagulation
Primary Prevention**

The use of long-term anticoagulation to reduce the risk for a first cardiogenic embolism in patients at increased risk because of conditions such as mechanical heart valves, atrial fibrillation, and cardiomyopathy is addressed in Chapters 25, 38, 63, and 82. The

combination of aspirin and clopidogrel is inferior to warfarin for stroke prevention in patients with atrial fibrillation (Fig. 59-5).¹⁸

Secondary Prevention

Evidence supporting the use of anticoagulation for prevention of recurrent stroke in patients without atrial fibrillation or other high-risk cardiogenic sources is uncertain, or the evidence suggests that the benefit does not outweigh the risk for warfarin-associated bleeding complications.

For patients with noncardioembolic stroke, WARSS (Warfarin-Aspirin Recurrent Stroke Study) directly compared warfarin (international normalized ratio [INR] of 2 to 3) and aspirin (325 mg/day).¹⁹ A nonsignificant advantage was associated with aspirin treatment (17.8% rate of recurrent stroke or death with warfarin versus 16.0% with aspirin, $P = 0.25$) (Fig. 59-6). The use of antiplatelet agents

rather than oral anticoagulation is recommended to reduce the risk for recurrent stroke and other cardiovascular events in patients with a noncardioembolic stroke or TIA.⁷

Although based on a post hoc analysis, data from WARSS were also evaluated to address the problem of "aspirin failures." This term is used variably to refer to patients taking aspirin who have no measurable platelet antiaggregant effect or to patients who have a recurrent ischemic event such as stroke despite treatment. The latter definition was used in the WARSS analysis. Of the patients who had a history of stroke before the study index stroke, those taking aspirin before random assignment (i.e., "aspirin failures") and randomly assigned to receive aspirin had a 31.8% rate of recurrent stroke as compared with a 16.9% rate in those who were randomly assigned to aspirin but had not been taking it before assignment (i.e., the rate of recurrent stroke was higher in those who had "failed" aspirin). The rate of recurrent stroke, however, was 29% in those who had failed aspirin and were randomly assigned to warfarin. Therefore based on the data from WARSS, despite a high rate of recurrent stroke in patients failing aspirin who were subsequently treated with aspirin, treatment with

warfarin showed no advantage. In addition, no data show that patients failing aspirin benefit from an alternative antiplatelet regimen.⁷

A retrospective data analysis suggested that patients with symptomatic, intracranial, large-vessel steno-occlusive disease benefited from warfarin as compared with aspirin.²⁰ This hypothesis was subsequently tested in the WASID (Warfarin-Aspirin Symptomatic Intracranial Disease) trial, in which warfarin (INR of 2 to 3) was compared with aspirin (1300 mg/day).²¹ The rate of recurrent ischemic stroke, intracerebral hemorrhage, or non-stroke-related vascular death did not differ between the two treatment regimens (22% with warfarin versus 21% with aspirin, $P = 0.83$), but the rate of major hemorrhage was higher with warfarin (8.3% versus 3.2%, $P = 0.01$). Because of a lack of efficacy and a higher rate of bleeding complications, warfarin should not generally be used for patients with symptomatic large-vessel intracranial steno-occlusive disease.⁷ The SAMMPRIS (Stenting and Aggressive Medical Management for Preventing Recurrent Stroke in Intracranial Stenosis) trial further found that aggressive medical management was superior to angioplasty/stenting in patients with symptomatic, large-vessel steno-occlusive disease because of a high early risk for stroke with endovascular treatment and because the risk for stroke with aggressive medical therapy alone was lower than expected (Fig. 59-7).²²

Angioplasty and stenting in patients with this condition who “fail” medical therapy may also be considered under the U.S. Food and Drug Administration (FDA) Humanitarian Device Exemption with local institutional review board approval; its use should be restricted, however, to those who have had recurrent strokes in the territory of the stenosed artery despite medical therapy, and it should not be used in the setting of an acute stroke.

Although a patent foramen ovale (PFO, with or without an atrial septal aneurysm) is found more commonly in young patients with cryptogenic stroke, optimal therapy for secondary stroke prophylaxis is uncertain. This is in part because the relationship between the presence of a PFO (whether large or small and with or without an atrial septal aneurysm) and the risk for recurrent stroke and death is not clear. A systematic literature review of 129 articles identified 4 meeting the minimal quality criteria and found, in comparison to those without a PFO, no significant increase in recurrent stroke or death for those

with a PFO (odds ratio [OR], 0.95; 95% CI, 0.62 to 1.44), a small PFO (OR, 1.23; 95% CI, 0.76 to 2.00), a large PFO (OR, 0.59; 95% CI, 0.28 to 1.24), or a combined PFO and atrial septal aneurysm (OR, 2.10; 95% CI, 0.86 to 5.06).²³ This finding agrees with the results of the subsequently reported PICSS (PFO in Cryptogenic Stroke Study), which found almost identical rates of recurrent stroke or death regardless of the presence of a PFO.²⁴ Essentially no prospective randomized trials have compared antiplatelet and anticoagulant therapy in this setting, and PICSS reported almost identical rates of recurrent stroke or death with aspirin or warfarin in those with and without a PFO.

Several randomized trials have assessed the potential benefits of endovascular PFO closure versus medical therapy and found no benefit of closure (see Chapter 62).²⁵⁻²⁷ The current FDA Humanitarian Device Exemption for endovascular PFO closure with a device designed for that purpose requires the patient to have failed best medical therapy. Whether endovascular PFO closure is of benefit even in this population is uncertain.

Patients with low-ejection fraction congestive heart failure are also at risk for systemic embolization, but data from large prospective randomized trials have not previously been available to determine optimal antithrombotic therapy. The WATCH (Warfarin and Antiplatelet Therapy in Chronic Heart Failure) trial compared open-label warfarin (target INR of 2.5 to 3.0) and double-blind treatment with either clopidogrel or aspirin in patients in sinus rhythm who had chronic congestive heart failure (ejection fraction <35%).²⁸ No differences were found between warfarin and aspirin (hazard ratio [HR], 0.98; 95% CI, 0.86 to 1.12; $P = 0.77$), between warfarin and clopidogrel (HR, 0.89; 95% CI, 0.68 to 1.16; $P = 0.39$), or between clopidogrel and aspirin (HR, 1.08; 95% CI, 0.83 to 1.40; $P = 0.57$) for the primary outcome (time until nonfatal stroke, nonfatal MI, or death). The trial also found no evidence that warfarin is superior to aspirin or that clopidogrel is superior to aspirin for prevention in stroke in patients with low-ejection fraction congestive heart failure. The WARCEF (Warfarin versus Aspirin in Reduced Cardiac Ejection Fraction) trial compared warfarin (target INR of 2.0 to 3.5) with aspirin (325 mg/day) in patients in normal sinus rhythm who had a reduced left ventricular ejection fraction.²⁹ Ischemic stroke, intracerebral hemorrhage, or death from any cause (primary outcome) occurred at a rate of 7.47 events per 100 patient-years with warfarin versus 7.93 with aspirin (HR with warfarin, 0.93; 95% CI, 0.79 to 1.10; $P = 0.40$). A reduction in ischemic stroke with warfarin was balanced by an increase in intracranial hemorrhage (Fig. 59-8). Taken together, WATCH and WARCEF found no reduction in stroke with warfarin versus aspirin in patients with congestive heart failure or a low ventricular ejection fraction.

FIGURE 59-7 Percutaneous transluminal angioplasty and stenting plus medical therapy versus medical therapy alone in patients with symptomatic, high-grade intracranial stenosis. Kaplan-Meier curves for the cumulative probability of the primary endpoint according to treatment assignment are shown. The primary endpoint was stroke or death within 30 days after enrollment or after a revascularization procedure for the qualifying lesion during the follow-up period or stroke in the territory of the qualifying artery beyond 30 days. The curves were truncated at 15 months because relatively few patients have been followed beyond this time and only two primary endpoint events have occurred beyond 15 months, both in the group receiving percutaneous transluminal angioplasty and stenting (PTAS) (one at 26.1 months and one at 26.2 months). The maximum duration of follow-up is 28.9 months for the group receiving medical management only and 28.1 months for the PTAS group. The inset shows the same data on an enlarged segment of the y axis. (From Chimowitz MJ, Lynn MJ, Derdeyn CP, et al: Stenting versus aggressive medical therapy for intracranial arterial stenosis. *N Engl J Med* 365:993, 2011.)

FIGURE 59-8 Warfarin versus aspirin in patients with heart failure and no atrial fibrillation. Cumulative incidence of the primary outcome is shown. The primary outcome was time to the first event in the composite endpoint of ischemic stroke, intracerebral hemorrhage, or death from any cause. (From Homma S, Thompson JLP, Pullicino PM, et al: Warfarin and aspirin in patients with heart failure and sinus rhythm. *N Engl J Med* 366:1859, 2012.)

The various inherited (e.g., protein C, protein S, or antithrombin III deficiency; factor V Leiden; or the prothrombin G20210A mutation) and acquired (e.g., lupus anticoagulant, anticardiolipin or antiphospholipid antibodies) coagulopathies are more commonly associated with venous than with arterial thrombosis (see also Chapter 82).^{2,7} Despite clear instances in which these types of disorders are associated with ischemic stroke, particularly in children or young adults, causal relationships remain controversial. For example, in APASS (Antiphospholipid Antibody Stroke Study), another substudy of WARSS, 41% of 1770 subjects were positive for one or more antiphospholipid antibodies.³⁰ Rates of recurrent thromboembolic events were somewhat higher in those who were antiphospholipid antibody positive, but there was no difference in outcome between antibody-positive patients who were treated with warfarin or aspirin. Patients with venous thromboembolic events who have an underlying coagulopathy or those with stroke or TIA otherwise fulfilling the criteria for antiphospholipid antibody syndrome (venous and arterial occlusive disease in multiple organs, miscarriages, and livedo reticularis) appropriately receive warfarin. Because coagulopathies (especially the genetic forms listed above) are more commonly associated with venous thromboses, cryptogenic stroke in this setting should prompt an evaluation for sources of potential paradoxical embolism. The yield of magnetic resonance imaging (MRI) of the pelvis and lower extremities is higher than that of Doppler ultrasound, so MRI should be considered in patients with a presumed paradoxical embolus.³¹ In the absence of antiphospholipid antibody syndrome, those with arterial stroke who are found to have only elevated antiphospholipid antibody levels may reasonably be treated with antiplatelet therapy.⁷

Hydroxymethylglutaryl-Coenzyme a Reductase Inhibitors (Statins) (See also Chapters 42 and 45)

Primary Prevention

Treatment of patients with coronary heart disease (CHD) or those at elevated risk for CHD with statins reduces not only cardiac events, but also the risk for a first stroke (Fig. 59-9).³² A meta-analysis of randomized trials of statins that included 165,792 subjects found that each 40-mg/dL decrease in low-density lipoprotein cholesterol was associated with a 21.1% (95% CI, 6.3% to 33.5%; $P = 0.009$) reduction in the risk for a first stroke (Fig. 59-10).³² Specific studies have shown a reduction in the risk for first stroke with statin treatment in diabetics,^{33,34} hypertensives,³⁵ and older adults.³⁶

JUPITER (Justification for the Use of Statin in Prevention: An Intervention Trial Evaluating Rosuvastatin) evaluated the effect of a statin in persons with higher than median (>2 mg/dL) high-sensitivity C-reactive protein who were not otherwise candidates for treatment.³⁷ The study found that statin treatment resulted in a 44% reduction in time to the primary endpoint (combined risk for MI, stroke, arterial revascularization, hospitalization for unstable angina, or death from cardiovascular causes; HR, 0.56; 95% CI, 0.46 to 0.69; $P < 0.00001$), including an approximate 50% reduction in stroke (Fig. 59-11). The implications

of the results of the trial for patient management are a subject of debate.² The benefit of stroke reduction with statin therapy may extend to those at lower (5% to 10% 5-year) risk for vascular events (Fig. 59-12).³⁸

Secondary Prevention

In contrast to the large amount of data showing a reduction in the risk for a first stroke in patients with CHD or those at high risk for CHD who are treated with a statin, less evidence supports statin treatment to reduce the risk for a second stroke. The HPS (Heart Protection Study) included 3280 subjects with a history of stroke (including 1820 with stroke and no history of CHD) who were treated with either a statin or placebo.³⁹ In those with a previous history of stroke, statin treatment reduced the frequency of MVEs (MI, stroke, revascularization procedure, or vascular death) by 20% but did not lower the risk for recurrent stroke (occurring in 10.5% of those treated with placebo versus 10.4% of those treated with the statin). The most important explanation might be that patients randomly assigned randomized an average of approximately 4 years after the index event. Most recurrent strokes occur soon (within the first few years), so those randomized in the HPS had a relatively low risk for recurrent stroke.

The SPARCL (Stroke Prevention with Aggressive Reduction in Cholesterol Levels) trial randomly assigned more than 4700 subjects

FIGURE 59-9 Meta-analysis of the effects of statins on stroke prevention. Results are from 24 trials that included 165,792 patients with fatal and nonfatal stroke. CVD = cardiovascular disease. (From Amarenco P, Labreuche J: Lipid management in the prevention of stroke: Review and updated meta-analysis of statins for stroke prevention. *Lancet Neurol* 8:453, 2009; data on LIPID and CARE with or without prior CVD from Vergouwen MD, de Haan RJ, Vermeulen M, Roos YB: Statin treatment and the occurrence of hemorrhagic stroke in patients with a history of cerebrovascular disease. *Stroke* 39:497, 2008.)

within 6 months of a noncardioembolic stroke or TIA and no known CHD to high-dose statin or placebo for a primary endpoint of the first occurrence of a nonfatal or fatal stroke.⁴⁰ Those randomized to high-dose statin treatment had a 16% relative reduction in nonfatal or fatal stroke, as well as a 35% relative reduction in major coronary events. Added to the previous data on prevention of a first stroke, SPARCL showed that treatment with a high-dose statin can reduce the risk for recurrent stroke after stroke or TIA (Fig. 59-13). On the basis of this trial, statin therapy with intensive lipid-lowering effects is recommended for patients with atherosclerotic ischemic stroke or TIA and without known CHD to reduce the risk for stroke and cardiovascular events.³ The results suggest that noncardioembolic stroke might be considered as a CHD equivalent because of the dramatic reduction in CHD events despite the subjects having no known CHD at the time of randomization.

Antihypertensives

Primary Prevention

Hypertension is one of the most important treatable risk factors for both ischemic stroke and parenchymal intracerebral hemorrhage (see Chapters 43 and 44). Guidelines indicate that the choice of a specific antihypertensive regimen must be individualized, but that the reduction in blood pressure is generally more important than the specific agent or agents used to achieve this goal.^{2,41} A meta-analysis of randomized controlled trials comparing antihypertensive drugs with placebo or no treatment of stroke, in which more than 73,500 participants and almost 2900 stroke events were included, found similar reductions in risk with angiotensin-converting enzyme (ACE) inhibitors (28%), beta-adrenergic receptor blockers (beta blockers) or diuretics (35%), and calcium channel antagonists (39%); the reductions in risk corresponded to reductions in blood pressure of 5/2, 13/6, and 10/5 mm Hg, respectively (Fig. 59-14).⁴² Further work now

FIGURE 59-11 Results of the JUPITER trial, in which the effects of statin treatment were evaluated in patients with high-sensitivity C-reactive protein greater than 2 mg/dL and no other indication for statin therapy. Numbers indicate point estimates; horizontal lines indicate 95% CI. (From Goldstein LB: JUPITER and the world of stroke medicine. *Lancet Neurol* 8:130, 2009; data from Ridker PM: Rosuvastatin in the primary prevention of cardiovascular disease among patients with low levels of low-density lipoprotein cholesterol and elevated high-sensitivity C-reactive protein: Rationale and design of the JUPITER trial. *Circulation* 108:2292, 2003.)

suggests that stroke reduction may be less in the setting of higher blood pressure variability.⁴³ Beta blockers, which are associated with higher variability in blood pressure than are other classes of antihypertensives, may be less effective.⁴⁴ Meta-analysis suggests that chlorthalidone may be more effective than hydrochlorothiazide in reducing cardiovascular events.⁴⁵

Secondary Prevention

Only limited data directly address the role of blood pressure treatment in secondary prevention among persons with a history of stroke or TIA. A systematic review focused on the relationship between blood pressure reduction and secondary prevention of stroke and

other vascular events, and included seven trials with a combined sample size of 15,527 participants with ischemic stroke, TIA, or intracerebral hemorrhage randomly assigned from 3 weeks to 14 months after the index event and observed for between 2 and 5 years.⁴⁶ Treatment with antihypertensive drugs was associated with significant reductions in all recurrent strokes (24%), nonfatal recurrent stroke (21%), MI (21%) (Fig. 59-15), and all vascular events (21%). Data on the relative benefits of specific antihypertensive regimens for secondary prevention of stroke are sparse. This meta-analysis found a reduction in recurrent stroke with diuretics (32%), and with diuretics and ACE inhibitors in combination (45%), but not with beta blockers or ACE inhibitors used alone.⁴⁶ The overall reductions in both stroke and all vascular events were related to the degree of blood pressure lowering.

Whether ACE inhibitors have a specific benefit in reducing the risk for recurrent stroke also remains uncertain. The HOPE (Heart Outcomes Prevention Evaluation) study compared the effects of an ACE inhibitor and placebo in high-risk persons and found a 24% reduction in the risk for stroke, MI, or vascular death in the 1013 patients with a history of stroke or TIA.⁷ PROGRESS (Perindopril Protection Against Recurrent Stroke Study) tested the effects of a blood pressure-lowering regimen, including an ACE inhibitor, in 6105 patients with stroke or TIA within the previous 5 years.⁷ Randomization was stratified by intention to use single (the ACE inhibitor) or combination (ACE inhibitor plus the diuretic indapamide) therapy in both hypertensive (>160 mm Hg systolic or >90 mm Hg diastolic) and nonhypertensive patients. The combination, which reduced blood pressure by an average of

Estimates of relative risk reduction

- 10% LDL reduction: relative risk reduction 7.5% (2.3-12.5) overall
relative risk reduction 13.5% (7.7-18.8) for primary prevention of stroke
- 1 mmol/L (39 mg/dL) LDL reduction: relative risk reduction 21.1% (6.3-33.5) overall
relative risk reduction 35.9% (21.7-47.6) for primary prevention of stroke

FIGURE 59-10 Cholesterol lowering with statins and risk for stroke. Inverse variance-weighted regression lines have been plotted after including all 24 trials (165,792 patients; solid line) and excluding those with clearly identified groups of patients in secondary stroke prevention (SPARCL; HPS, LIPID, and CARE subgroups with previous cerebrovascular disease; dashed line). The underlying causes of stroke are important when considering the association between lipid and stroke risk, so the SPARCL results are also shown in accordance with the presence or absence of documented CS. Data for the SEARCH trial were presented at the 2008 American Heart Association meeting. CS = carotid stenosis; LDL = low-density lipoprotein. (From Amarenco P, Labreuche J: Lipid management in the prevention of stroke: Review and updated meta-analysis of statins for stroke prevention. *Lancet Neurol* 8:453, 2009.)

12/5 mmHg, yielded a 43% reduction in the risk for recurrent stroke and a 40% reduction in the risk for major vascular events, with the effect present in both hypertensive and normotensive groups. Yet no significant benefit was found with either antihypertensive alone. Specific patient characteristics and comorbid conditions should guide the choice of a specific antihypertensive regimen.

MANAGEMENT OF ACUTE ISCHEMIC STROKE

As with acute coronary syndromes, time is of the essence in the treatment of patients with acute ischemic stroke. Stroke has a large variety of causes and potential pathophysiologic mechanisms that should be used to determine the rationale for using secondary preventive therapies, some of which were reviewed in the preceding sections. A variety of conditions may cause symptoms and signs that can be mistaken for those of a stroke. In the period immediately following the onset of ischemic symptoms, however, evaluation should promptly determine whether the patient should receive reperfusion therapy.

Although not used diagnostically, the National Institutes of Health Stroke Scale (NIHSS) is both a reliable and valid stroke assessment scale and is now commonly used as a measure of stroke severity and to monitor stroke patients for clinical worsening or improvement.⁴⁷ As reflected later in this chapter, the NIHSS score is important for determining a patient's candidacy for intravenous tissue plasminogen activator (IV t-PA).

Intravenous Recombinant Tissue Plasminogen Activator

IV recombinant t-PA (rt-PA) is currently the only specific treatment of acute ischemic stroke that has received approval from the FDA. The treatment is aimed at lysis of a clot occluding a cerebral artery. Based on the pivotal NIH-sponsored randomized clinical trial, treatment of appropriate patients is associated with an approximate 13% absolute (32% relative) increase in the proportion of patients free of disability 3 months later.⁴ Benefits are similar in patients with ischemic stroke involving small penetrating arteries and in those with occlusion of larger intracranial arteries. Although treatment is also associated with an increase in the risk for hemorrhage (6.4% risk for symptomatic intracerebral hemorrhage with treatment versus 0.6% with placebo, 2.9% risk for fatal hemorrhage versus 0.3% with placebo), the overall benefit is maintained despite these adverse events. The drug must be given within 4.5 hours of the onset of symptoms, which means that the patient must generally arrive at a properly equipped and organized hospital within 3.5 hours of symptom onset to have the necessary evaluations completed, including brain computed tomography (CT) to exclude hemorrhage or other conditions. Within this "window," the sooner treatment can be initiated, the greater the

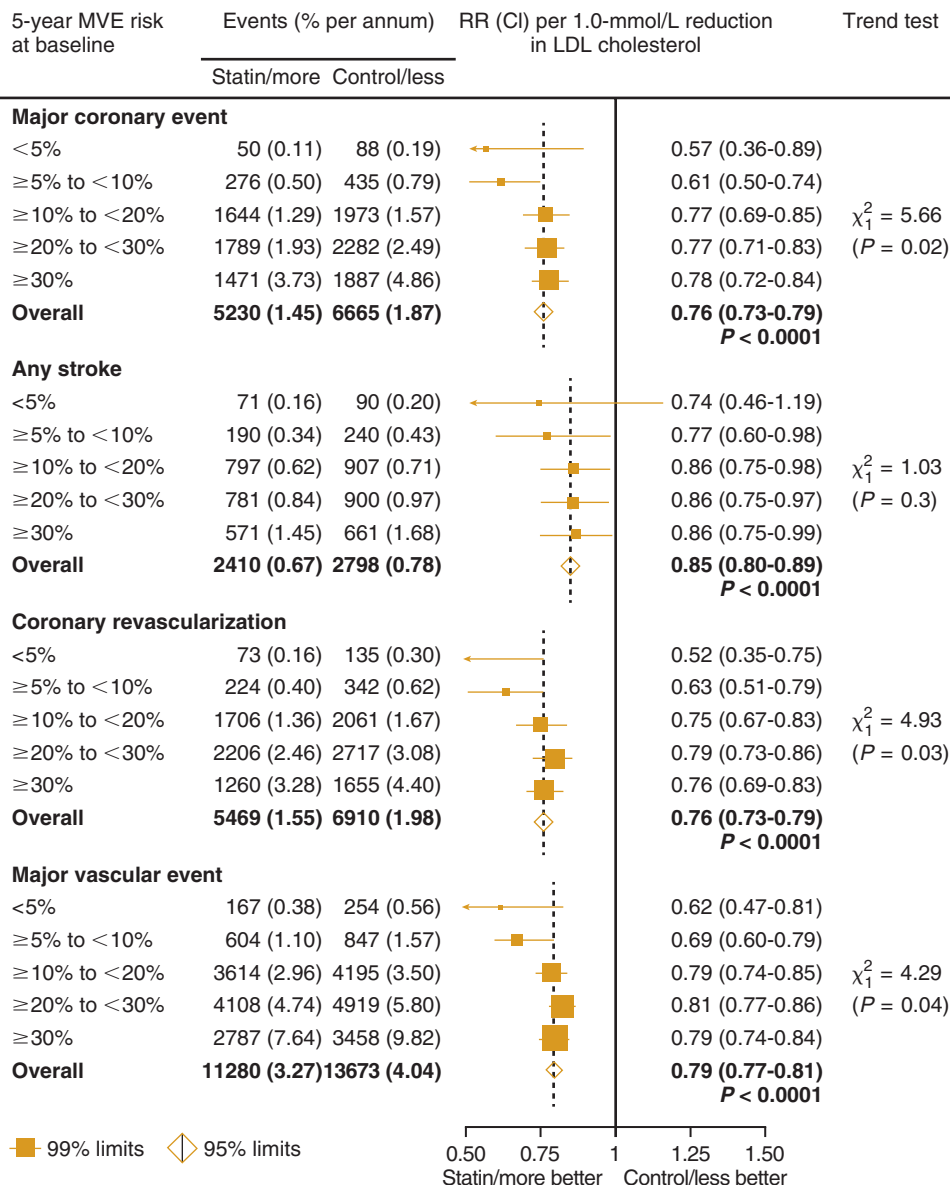

FIGURE 59-12 Effects on major coronary events, strokes, coronary revascularization procedures, and major vascular events per 1.0-mmol/L reduction in low-density lipoprotein cholesterol at different levels of risk. MVE = major vascular event. (From Cholesterol Treatment Trialists' [CTT] Collaborators: The effects of lowering LDL cholesterol with statin therapy in people at low risk of vascular disease: Meta-analysis of individual data from 27 randomised trials. *Lancet* 380:581, 2012.)

likelihood of a favorable response.⁴⁸ To use the drug safely, a strict protocol needs to be followed closely and patients must be selected carefully (Tables 59-2 and 59-3).⁴ Although recommended by the AHA/ASA, treatment with IV t-PA between 3 and 4.5 hours after the onset of symptoms has not been approved by the FDA. The development of organized systems of stroke care has been advocated to rapidly perform the necessary clinical evaluations, minimize delays in treatment, make certain that other interventions associated with improved outcomes are followed, and ensure that patients receive appropriate secondary prevention.⁴⁹

Up to a third of patients may have arterial reocclusion early after intravenous thrombolysis. One study has suggested facilitation of clot lysis by concomitant exposure to the ultrasound waves provided by transcranial Doppler, which can also be used to monitor clot dissolution.⁵⁰ A prospective trial is evaluating the usefulness of this approach.

Endovascular Therapy

Catheter-based, endovascular approaches for acute reperfusion have the theoretical advantages of allowing direct clot visualization and of localized rather than systemic administration of thrombolytics, as well

as the opportunity for mechanical clot disruption. But no prospective randomized trials have shown an advantage of endovascular therapy compared with IV-tPA as first-line therapy in patients with acute ischemic stroke. In addition, endovascular therapy requires immediate access to neurovascular interventionalists, is not generally feasible in patients with distal arterial occlusions, and might entail longer times until reperfusion (related to the need for access to an interventional suite, catheter placement time, etc.).

FIGURE 59-13 Effect of statin therapy on stroke in patients with a recent stroke or TIA. The Kaplan-Meier curve for stroke or TIA in SPARCL is shown. The data report an intention-to-treat analysis with prespecified adjustments for geographic region, entry event, time since the entry event, sex, and baseline age for the first occurrence of a fatal or nonfatal stroke or TIA. (From Amarenco P, Bogousslavsky J, Callahan A III, et al: High-dose atorvastatin after stroke or transient ischemic attack. *N Engl J Med* 355:549, 2006.)

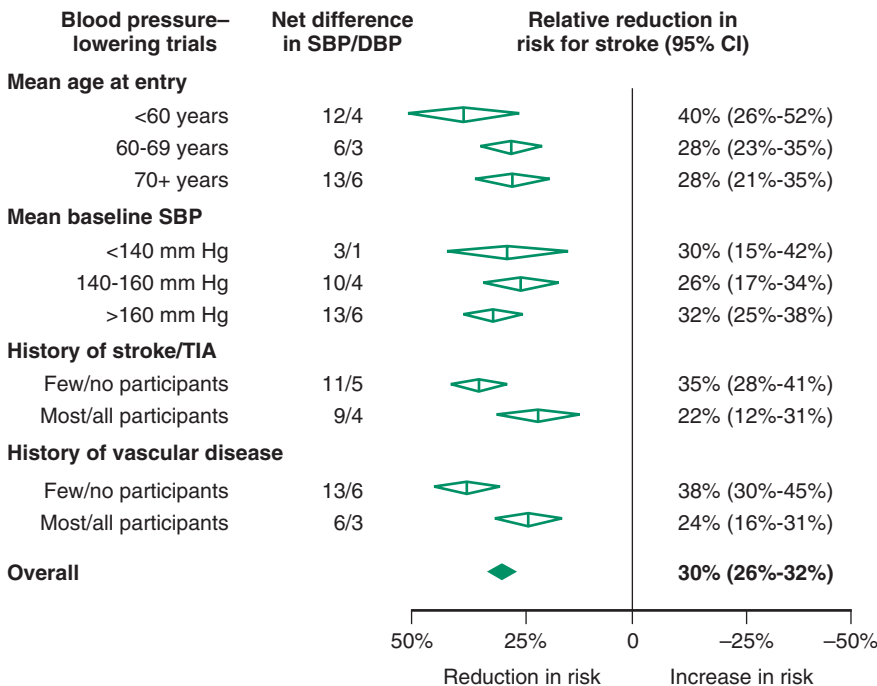

FIGURE 59-14 Randomized controlled trials comparing antihypertensive drugs with a placebo (or no treatment) by subgroup. The meta-analyses of blood pressure-lowering trials were stratified into subgroups on the basis of mean age of trial participants at entry, baseline systolic blood pressure level, and whether trial participants predominantly had a history of stroke/TIA or vascular disease. The diamonds are centered on the pooled estimate of effect and represent 95% CIs. The solid diamond represents the pooled relative risk and 95% CI for all contributing trials. DBP = diastolic blood pressure; SBP = systolic blood pressure. (From Lawes CM, Bennett DA, Feigin FL, Rodgers A: Blood pressure and stroke: An overview of published reviews. *Stroke* 35:1024, 2004.)

Prospective randomized data comparing intra-arterial thrombolysis with nonthrombolytic medical therapy have been derived primarily from a single clinical trial.⁵¹ This study evaluated intra-arterial thrombolysis with prourokinase in patients within 6 hours of angiographically proven proximal middle cerebral artery occlusion and found a significant improvement in 3-month outcome (40% of treated versus 25% of control patients had little or no disability) despite a trend toward an increase in symptomatic intracerebral hemorrhage (10% versus 2%, respectively). Prourokinase has not been approved by the FDA and is not currently available in the United States. Intra-arterial rt-PA is commonly used for this purpose in patients who do not qualify for treatment with IV rt-PA (most frequently because of arriving at the hospital too late) and otherwise fulfill the inclusion criteria for the cited prourokinase trial. In addition to patients with middle cerebral artery occlusions up to 6 hours earlier, based on case series data, selected patients with basilar artery occlusion up to 12 hours or more earlier may also be treated with this approach. The IMS-3 (Interventional Management of Stroke-3) trial assessed rescue endovascular therapy in patients with persistent arterial occlusion after primary treatment with IV t-PA. The trial was stopped by the NIH before the planned enrollment had been completed because of futility.⁵²

Mechanical clot retrieval has the theoretical advantage of avoiding the risk for bleeding associated with thrombolytic drugs. The "Merci" clot retriever was the first device approved by the FDA for removal of blood clots from brain blood vessels (but not as a specific treatment of acute stroke). This approval was based on the results of a noncontrolled case series involving 151 enrolled (141 of whom could be treated) patients with proximal (internal carotid, middle cerebral, or vertebrobasilar) arterial occlusions within 6 hours (mean of 4.3 hours to catheterization).⁵³ Recanalization was achieved in 48%, of whom 30% died or had a second stroke or MI within 30 days. Approximately 30% died within 90 days, but 46% of those surviving to 90 days had little or no disability. Procedural complications occurred in 13% (six arterial perforations, four arterial dissections, three cases of embolization to another artery, three subarachnoid hemorrhages, and three groin hematomas), with 28% having asymptomatic intracerebral hemorrhages and 8% having symptomatic hemorrhages. The frequency of parenchymal hemorrhages might at first seem surprising, but the arterial endothelium can be subject to ischemia-related damage, and reperfusion of a damaged artery (with or without a thrombolytic) can lead to bleeding. This study had no concurrent controls, thus leaving open the question of whether outcomes would be similar, better, or worse than with other reperfusion treatments. Two other devices (Solitaire, Trevo) have been directly compared with the Merci device and were found to have better recanalization rates and clinical outcomes^{54,55}; these and an additional device (Penumbra) have also gained FDA approval as tools for removing thrombi from brain blood vessels. This approach has the same logistic limitations as endovascular thrombolytic therapy, but offers the possibility of treating selected patients who cannot be treated with a thrombolytic drug (e.g., patients already anticoagulated, recently having undergone an operation or invasive procedure, or with an embolus complicating cardiac or other catheterization after the catheter sheath has been removed).

Other Measures for Treatment of Stroke

Several other important questions often arise in the management of patients with acute ischemic stroke, as well as other interventions that are generally used even without definitive supporting data.

Anticoagulation and Platelet Antiaggregant Therapy

The indications for acute anticoagulation of patients with ischemic stroke are extremely limited. The most recent AHA/American Academy of Neurology guidelines reflect this view and specifically indicate that emergency

anticoagulation with the goal of improving neurologic outcomes or preventing early recurrent stroke is not recommended for the treatment of patients with acute ischemic stroke, that urgent anticoagulation is not recommended for the treatment of patients with moderate to severe stroke because of a high risk for intracranial bleeding complications, and that initiation of anticoagulant therapy within 24 hours of treatment with IV rt-PA is not recommended.⁵⁶ Patients with atrial fibrillation-associated stroke benefit from long-term anticoagulation, unless contraindicated because of high bleeding risk (e.g., previous intracerebral hemorrhage, falls).³ The risk for early recurrence in patients with stroke related to atrial fibrillation is generally low ($\approx 0.3\%$ to 0.5% per day for the first 2 weeks), so the timing of initiation of anticoagulation needs to be balanced against the risk for bleeding. Those with large strokes and those with uncontrolled hypertension generally have the highest risk for spontaneous hemorrhagic transformation of an ischemic stroke.

The use of anticoagulants in patients with stroke related to infective endocarditis is problematic (see also Chapter 64). Systemic embolization occurs in 22% to 50% of patients with infective endocarditis, with up to 65% of emboli affecting the central nervous system, most of which (90%) involve the middle cerebral artery.⁵⁷ No benefit of anticoagulation has been demonstrated in patients with native valve endocarditis, and it is not generally recommended for at least the first 2 weeks of antibiotic therapy in patients with stroke related to *Staphylococcus aureus* prosthetic valve endocarditis.⁵⁷ Of particular concern is the possible development of mycotic intracranial aneurysms. These aneurysms are often multiple and can be either asymptomatic, associated with focal neurologic signs, or because they most commonly affect distal branches of the middle cerebral artery, associated with signs and symptoms of subarachnoid hemorrhage or a sterile meningitis.⁵⁷ Although CT angiography (in patients without renal insufficiency) or MR angiography can be useful screening tests in patients with symptoms suggesting the presence of a mycotic aneurysm, because distal portions of the artery are most commonly affected, catheter angiography is the "gold standard" for detection of these lesions (distal portions of the middle cerebral artery can be difficult to visualize with CT or MR angiography). Management of patients with intracranial mycotic aneurysms is complex, and many regress with antibiotic treatment. Depending on a variety of factors, surgical clipping or endovascular obliteration can also be considered. Anticoagulation is generally avoided in patients with known mycotic aneurysms because of their propensity to rupture.

As reflected earlier, the use of platelet antiaggregants reduces the risk for recurrent stroke in patients with a history of ischemic stroke or TIA. In the acute setting, aspirin initiated within 48 hours of acute ischemic stroke may provide benefit (these platelet antiaggregant drugs are prohibited for the first 24 hours in patients treated with IV rt-PA). A combined analysis of two relevant trials found that treatment with aspirin (160 mg or 325 mg daily) was associated with a small but statistically significant reduction consisting of 9 (± 3) fewer deaths or nonfatal strokes per 1000 treated patients.⁵⁶ The CHANCE (Clopidogrel in High-Risk Patients with Acute Nondisabling Cerebrovascular

Comparison: 01 After stroke/TIA
Outcome: 01 Stroke, fatal and nonfatal

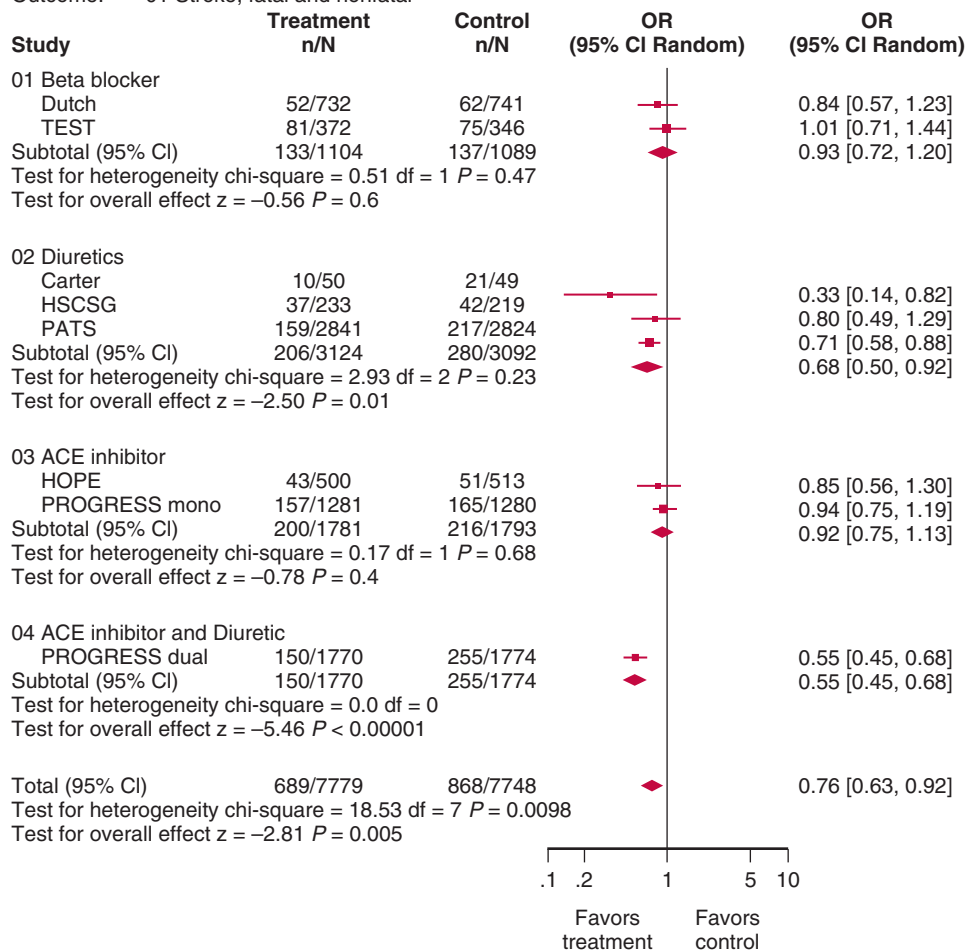

FIGURE 59-15 Forrest plot of the effect of antihypertensive therapy in patients with previous stroke or TIA on subsequent fatal and nonfatal stroke. (From Rashid P, Leonardi-Bee J, Bath P: Blood pressure reduction and secondary prevention of stroke and other vascular events: A systematic review. *Stroke* 34:2741, 2003.)

Events) trial, conducted in China, suggests that a short course of aspirin plus clopidogrel may decrease the risk of early recurrent stroke in patients with minor ischemic stroke or high-risk TIA. Whether these results are generalizable to other populations is uncertain.⁵⁸

Blood Pressure Management

Management of blood pressure in the setting of acute ischemic stroke remains largely empiric. Treatment of elevated blood pressure in patients who might otherwise be candidates for IV rt-PA differs from that in patients who are not thrombolytic candidates, and follows a specific protocol (Tables 59-4 and 59-5).⁴ Relatively aggressive treatment of elevated blood pressure is used in patients who have been treated with a thrombolytic because of an increased risk for bleeding complications associated with uncontrolled hypertension.

Several lines of evidence suggest cautious blood pressure management in non-thrombolytic-treated patients with acute ischemic stroke who do not have malignant hypertension (i.e., in patients with hypertensive encephalopathy, aortic dissection, acute renal failure, acute pulmonary edema, acute MI, or high blood pressure $>220/120$ mmHg).⁵⁹ Cerebral autoregulation maintains constant cerebral blood flow (CBF) despite fluctuations in systemic blood pressure. CBF is determined by dividing cerebral perfusion pressure (generally, mean arterial pressure [MAP]) by cerebrovascular resistance (CVR).⁶⁰ As reflected by this relationship, decreases in MAP lead to dilation of cerebral arterioles (decreased CVR), thereby keeping CBF constant. The local acidosis that accompanies brain ischemia leads to maximal vasodilation. As a result, decreases in MAP are directly reflected as changes in local CBF (if CVR

TABLE 59-2 Characteristics of Patients with Ischemic Stroke Who Could Be Treated with Intravenous Tissue Plasminogen Activator Within 3 Hours of Symptom Onset

Inclusion Criteria
Diagnosis of ischemic stroke causing measurable neurologic deficit Onset of symptoms <3 hr before beginning treatment Age ≥18 yr
Exclusion Criteria
Head trauma or previous stroke in the previous 3 mo Symptoms suggesting subarachnoid hemorrhage Arterial puncture at noncompressible site in the previous 7 days History of previous intracranial hemorrhage Elevated blood pressure (systolic >185 mmHg or diastolic >110 mmHg) Evidence of active bleeding on examination Acute bleeding diathesis, including but not limited to Platelet count <100,000/mm ³ Heparin received within 48 hr resulting in an aPTT greater than the upper limit of normal Current use of anticoagulant with an INR >1.7 or PT >15 sec Blood glucose concentration <50 mg/dL (2.7 mmol/L) CT demonstrating multilobar infarction (hypodensity >1/3 cerebral hemisphere)
Relative Exclusion Criteria
Recent experience suggesting that under some circumstances—with careful consideration and weighing of risk to benefit—patients may receive fibrinolytic therapy despite one or more relative contraindications. Consider the risk-to-benefit ratio of rt-PA administration carefully if any of these relative contraindications is present Only minor or rapidly improving stroke symptoms (clearing spontaneously) Seizure at onset with postictal residual neurologic impairments Major surgery or serious trauma within the previous 14 days Recent gastrointestinal or urinary tract hemorrhage (within the previous 21 days) Recent acute MI (within the previous 3 mo)

aPTT = activated partial thromboplastin time; PT = prothrombin time.

From Jauch EC, Cucchiara B, Adeoye O, et al: Part 11: Adult stroke. 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation* 122(18 Suppl 3):S818, 2010.

TABLE 59-3 Additional Criteria for Patients Who Are Candidates for Treatment Between 3 and 4.5 Hours of Symptom Onset

Inclusion Criteria
Diagnosis of ischemic stroke causing measurable neurologic deficit Onset of symptoms 3 to 4.5 hours before beginning treatment
Relative Exclusion Criteria
Age >80 yr Severe stroke (NIHSS >25) Taking an oral anticoagulant regardless of INR History of both diabetes and previous ischemic stroke
Notes:
The checklist includes some FDA-approved indications and contraindications for the administration of rt-PA for acute ischemic stroke. Recent guideline revisions have modified the original FDA criteria. A physician with expertise in acute stroke care may modify this list Onset time is either witnessed or last known normal In patients without recent use of oral anticoagulants or heparin, treatment with rt-PA can be initiated before the availability of coagulation study results, but should be discontinued if the INR is >1.7 or PT is elevated by local laboratory standards In patients without a history of thrombocytopenia, treatment with rt-PA can be initiated before availability of the platelet count, but should be discontinued if it is <100,000/mm ³

NIHSS = National Institutes of Health Stroke Scale; P = prothrombin time.

From Jauch EC, Cucchiara B, Adeoye O, et al: Part 11: Adult stroke. 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation* 122(18 Suppl 3):S818, 2010.

TABLE 59-4 Potential Approaches to Arterial Hypertension in Patients with Acute Ischemic Stroke Who Are Potential Candidates for Acute Reperfusion Therapy

Patient otherwise eligible for acute reperfusion therapy except that BP is >185/110 mmHg: Labetalol, 10-20 mg IV over 1-2 min; may repeat once, or Nicardipine, 5 mg/hr IV; titrate up by 2.5 mg/hr every 5-15 min; maximum, 15 mg/hr; when desired BP reached, lower to maintain BP in proper limits, or Other agents (hydralazine, enalaprilat, etc) may be considered when appropriate If BP is not maintained at or below 185/110 mmHg, do not administer rt-PA Management of BP during and after rt-PA or other acute reperfusion therapy: Monitor BP every 15 min for 2 hr from the start of rt-PA therapy, then every 30 min for 6 hr, and then every hour for 16 hr If systolic BP 180-230 mmHg or diastolic BP 105-120 mmHg: Labetalol, 10 mg IV, followed by continuous IV infusion at 2-8 mg/min, or Nicardipine, 5 mg/hr IV; titrate up to desired effect by 2.5 mg/hr every 5-15 min; maximum, 15 mg/hr If BP not controlled or diastolic BP >140 mmHg, consider sodium nitroprusside
--

BP = blood pressure.

From Jauch EC, Cucchiara B, Adeoye O, et al: Part 11: Adult stroke. 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation* 122(18 Suppl 3):S818, 2010.

TABLE 59-5 Approach to Arterial Hypertension in Patients with Acute Ischemic Stroke Who Are Not Potential Candidates for Acute Reperfusion Therapy

Consider lowering blood pressure in patients with acute ischemic stroke if systolic blood pressure >220 mmHg or diastolic blood pressure >120 mmHg Consider blood pressure reduction as indicated for other concomitant organ system injury: Acute myocardial infarction Congestive heart failure Acute aortic dissection A reasonable target is to lower blood pressure by 15% to 25% within the first day
--

From Jauch EC, Cucchiara B, Adeoye O, et al: Part 11: Adult stroke. 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation* 122(18 Suppl 3):S818, 2010.

remains constant). Therefore lowering blood pressure may further compromise an already ischemic brain and potentially increase the size of the stroke. If treatment is necessary, precipitous drops should be avoided.

Stroke after Percutaneous Coronary Interventions and Thrombolytic Treatment of Myocardial Infarction

Although occurring infrequently, stroke can be a major complication of percutaneous coronary interventions (PCIs). The same principles outlined for the management of acute stroke in other settings apply. If neurologic symptoms are recognized while the catheter sheath is still in place, the patient could receive IV rt-PA, provided that all the other inclusion criteria are met and the patient has no other contraindications to the therapy. If symptoms are first noted after the catheter sheath has been removed, the patient could be evaluated for catheter-based, endovascular treatment. It is important to have a system in place to ensure that patients with stroke after PCI can be evaluated and treated rapidly.

Intracerebral hemorrhage following administration of a thrombolytic for acute MI is another serious treatment-related complication. The infusion should be stopped and heparin discontinued in any patient in whom acute neurologic symptoms develop. Because these symptoms might result from either hemorrhage or ischemia, a brain-imaging study is mandatory before proceeding with further treatment. Treatments to reduce the amount of thrombolytic-associated

intracerebral hemorrhage once it has occurred are not well established. Administration of cryoprecipitate and/or fresh frozen plasma has been advocated. Those with brainstem compression related to cerebellar hemorrhage may benefit from surgical evacuation of the hematoma. Patients should be transferred to a setting with expertise in neurologic intensive care as soon as feasible.

FUTURE PERSPECTIVES

Much of the greater than 30% reduction in stroke mortality that has occurred in the United States over the last decade is associated with more effective prevention. Continued emphasis on prevention promises to have the greatest impact on further improvements. Additional work needs to be done to establish the clinical usefulness of advanced neuroimaging to better select patients for acute reperfusion interventions. Whether endovascular therapy results in better outcomes in subgroups of patients with acute stroke who cannot be treated with IV t-PA needs to be established. New approaches to poststroke recovery offer the potential of improved outcomes in those with functional deficits persisting after the acute period.

REFERENCES, 1363

Peripheral vascular disease is a general term that includes pathologic processes affecting arteries, veins, and lymphatics ([see also Chapter 58](#)). This chapter focuses on catheter-based endovascular treatment of large and medium-sized arteries predominantly affected by atherosclerosis, as well as large vein obstruction secondary to chronic disease. Although peripheral artery disease (PAD) refers to lower limb arterial disease, it is sometimes used to describe arterial disease in the large and medium arteries of the upper limbs, cervical arteries, and aortomesenteric arteries. The incidence and prevalence of PAD increase with age and with other risk factors for atherosclerosis. Thus these two demographic forces are likely to increase PAD in industrialized and rapidly modernizing nations throughout the world where average age is increasing and risk factors are prevalent.

Increasing awareness of PAD, the impact that PAD has on cardiovascular risk and quality of life, and the rapid development of percutaneous techniques for revascularization continue to accelerate the number of endovascular procedures for PAD. Appropriate use of this expensive technology requires a clear understanding of the goals of medical and revascularization therapies.

APPROACH TO THE PATIENT WITH PERIPHERAL ARTERY DISEASE

Chronic PAD is either asymptomatic or associated with symptoms such as claudication, critical limb ischemia, or embolic infarction of a distal organ (e.g., stroke). Asymptomatic disease is common. In the lower extremities, asymptomatic disease occurs in at least half and in as many as 80% of subjects with abnormal functional test results indicative of obstructive arterial disease (e.g., abnormal ankle-brachial index [ABI]). Even asymptomatic disease is a marker for elevated cardiovascular risk.¹⁻⁴ Therefore a prime goal of therapy is intensive modification of atherosclerosis risk factors to reduce the risk for myocardial infarction and stroke, which are the most common causes of death in patients with PAD.^{3,5}

Claudication classically refers to leg discomfort or pain related to exercise and relieved by rest, but it is also used to describe discomfort in the upper limbs caused by effort-related ischemia. Claudication affects function (the ability to walk or use a limb) and quality of life. Hence treatment of claudication aims to improve function and reduce discomfort at the maximum level of activity desired by a patient. The two most important lifestyle interventions for claudication are to stop cigarette smoking and to start a regular walking regimen. Together, these interventions reduce the mechanisms

responsible for the progression of disease and favorably change arterial biology—for example, vasodilator function, muscle function, and angiogenesis.^{2,3,5} It is important to tell patients that the pain or discomfort associated with claudication is not harmful and that once this discomfort abates with rest, they should continue to push their activity again to improve endurance. Revascularization strategies aim to improve arterial blood flow in obstructed large and medium-sized arteries when noninvasive therapies fail. Catheter-based intervention, when indicated, should be deployed together with lifestyle and medical treatment.⁶

Critical limb ischemia refers to PAD with ischemic pain at rest or tissue loss (e.g., ulcer or gangrene).^{2,3} This scenario has clinical urgency because of near-term risk for limb jeopardy requiring major amputation. Major amputation in the lower limbs refers to amputation at or above the level of the ankle and requires a prosthesis for the patient to walk.³ It is disfiguring, and higher levels of amputation have greater impact on functional independence of the patient. In contrast, minor amputations (e.g., toe or transmetatarsal) usually have little impact on the patient's ability to walk. Catheter-based therapies for critical limb ischemia aim to improve blood flow to heal ischemic tissue, to salvage the limb (prevent major amputation), or to enable a lower level of amputation that might have less impact on the patient's ability to walk.

Cervical carotid, vertebral, and subclavian disease, although often asymptomatic, can lead to artery-to-artery embolism with transient ischemic attack and stroke. The risk for major stroke is high shortly after a symptomatic event but less so several months after an event or with asymptomatic disease.⁷ Mesenteric and renal artery disease affects the function of these organs. Chronic ischemia of the gut causes postprandial abdominal discomfort and food avoidance leading to weight loss, but it may progress to frank mesenteric infarction with a high mortality rate.⁸ Renal artery stenosis can precipitate hypertensive crises associated with pulmonary edema, hypertension resistant to treatment, and rapidly worsening renal dysfunction.⁹

Symptomatic disease that threatens a distal organ (e.g., critical limb ischemia, transient ischemic attack, or mesenteric angina) justifies a more aggressive approach because these manifestations entail the highest risk for functional loss and death without treatment. PAD associated with less threatening clinical scenarios (e.g., claudication) may allow a less aggressive approach with more time to implement lifestyle and medical therapies ([Fig. 60-1](#)). There is rarely justification for catheter-based or surgical revascularization of asymptomatic lower or upper limb PAD, mesenteric disease, or subclavian or vertebral artery disease. The value of revascularizing asymptomatic

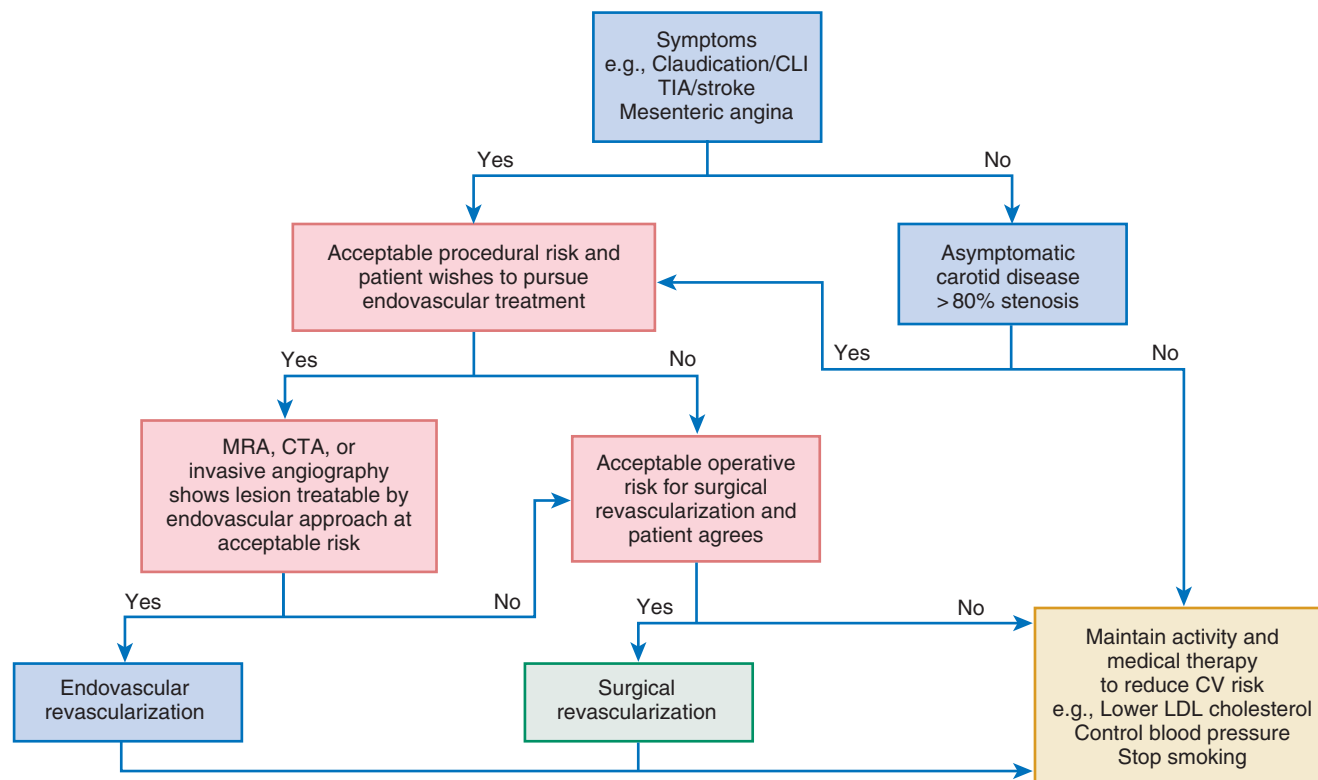

FIGURE 60-1 Approach to a patient with PAD. This strategy is based on assessment of the risk for adverse events with and without treatment by taking into consideration procedural or operative risks and the patient's informed decision to proceed with revascularization. CLI = critical limb ischemia; CTA = CT angiography; CV = cardiovascular; LDL = low-density lipoprotein; MRA = MR angiography; TIA = transient ischemic attack.

extracranial carotid disease, beyond medical therapy, is uncertain, although it is supported by recent guidelines involving patients at higher risk for stroke and low risk for periprocedural adverse events.⁷

Quality of Evidence Evaluating Endovascular Treatments

In contrast to coronary disease, only a few well-controlled studies have evaluated endovascular treatment of PAD and venous disease. Many studies are single arm, and most focus on patency (lack of restenosis) and repeated revascularization over a relatively short period. Although these endpoints provide information on the mechanisms likely to lead to improved control of symptoms, function, quality of life, and tissue preservation, they do not provide direct guidance on symptoms and function in patients with claudication or critical limb ischemia. Interventionalists should recognize the limitations in many studies and encourage future studies to address patient-oriented endpoints and adjudicated cardiovascular outcomes.^{10,11}

ENDOVASCULAR TECHNOLOGIES

Balloon Angioplasty

Balloon angioplasty remains the mainstay of endovascular intervention for PAD and venous disease (Fig. 60-2). Angioplasty remodels the artery by expansion and accommodates the atherosclerotic plaque to expand the vessel lumen. This procedure usually causes dissection of the plaque that may or may not impair blood flow. Angioplasty is limited in the short term by acute recoil of the artery and flow-limiting dissections, which may cause abrupt closure of the artery. In the intermediate time frame, overexuberant neointimal hyperplasia and negative remodeling of the artery may lead to symptomatic restenosis. Despite these limitations, balloon angioplasty can achieve durable results, particularly with shorter lesions, and is less

likely than stenting to obstruct side branches associated with the lesion. Most operators use prolonged inflations (a minute or more).¹² Both rapid-exchange and over-the-wire platforms are available, as well as short and long shaft lengths for lesions close or farther away from the access site.

Bare Metal Stents

Bare metal stents come in two types—either balloon-expandable (Fig. 60-3) or self-expandable stents (Fig. 60-4). Stent implantation requires aspirin therapy and a thienopyridine (e.g., clopidogrel), although the evidence for dual antiplatelet therapy is derived largely by extrapolation from the coronary stent literature.

Balloon-expandable stents have greater radial strength and are less likely to move on deployment—which is important for ostial placement. Such stents can be crushed by external compression and are therefore avoided outside the torso. They are sometimes used to treat tibial disease, but only for critical limb ischemia, for which long-term patency may be less of an issue once tissue healing has occurred.

Self-expanding stents were originally made of stainless steel but are now more commonly made of nitinol.¹² Nitinol stents re-expand on compression and are therefore used outside the torso, where external compression is more likely to occur. They may also be used in tortuous arteries, where they probably conform better than balloon-expandable stents do. Their lower radial strength, however, increases the risk for recoil. More recent designs are more durable and less likely to fracture.^{12,13} Nitinol stents cannot be overdilated if the stent is undersized for the artery, which may lead to stent malapposition or even embolization.

Drug-Eluting Peripheral Stents

Earlier attempts at coating peripheral self-expanding stents were initially associated with less restenosis in the short term but were unsuccessful in longer follow-up, partly because of inferior stent platforms

FIGURE 60-2 Treatment of a mid-superficial femoral artery stenosis (A), with balloon angioplasty alone (B), with an excellent final result (C).

FIGURE 60-3 Treatment of left common iliac stenosis with a balloon-expandable stent from the contralateral right femoral artery. A, Serial stenoses in the left common iliac artery (arrow). B, Balloon-expandable stent deployment. C, Final angiogram.

prone to fracture. More durable stent designs¹²⁻¹⁴ and drug elution with everolimus¹⁵ or paclitaxel¹⁶ offer lower rates of restenosis, although the magnitude of long-term benefit remains under investigation. The duration of dual antiplatelet therapy required for these stents is also uncertain, but recent randomized trials have generally used 2 to 6 months of treatment with a thienopyridine.^{15,16}

Covered Stents

Stents covered with or sandwiching a polymer such as polytetrafluoroethylene (PTFE) have proved very useful for treating perforations related to endovascular treatment or excluding aneurysms (Fig. 60-5). Some trials have suggested that these designs may offer lower restenosis rates when treating femoral and iliac artery disease,^{17,18} but the benefit may reflect unusually high rates of restenosis in the control groups of these studies. Disadvantages of covered stents include unintentional occlusion of important branch vessels, concerns about the risk for late stent thrombosis, and whether restenosis was merely delayed rather than prevented.

Drug-Eluting Balloons

Balloons coated with antirestenosis agents (drug-eluting balloons) represent an exciting development over the last few years. This technology uses a non-stent-related method to deliver drugs such as paclitaxel into the arterial wall after conventional angioplasty treatments. Initial studies have shown great promise for this technology in preventing restenosis in the infraginal arteries (femoral and below).¹⁹⁻²³ The risk for restenosis tends to lie between that of plain balloon angioplasty and drug-eluting stenting. Such a result is not surprising because this technology does not combat arterial recoil, an important contributor to late loss of lumen diameter. The durability of this treatment versus plain balloon angioplasty and bare metal or drug-eluting stents requires further definition. Similarly, the need for dual antiplatelet therapy is uncertain.

Thrombolysis and Thrombectomy

Catheter-directed thrombolysis is an important adjunctive therapy for arterial thrombosis, stent thrombosis, and occlusive thrombotic

FIGURE 60-4 Treatment of a superficial femoral artery occlusion with a self-expandable nitinol stent. **A**, A wire approaches the occluded segment. **B-D**, The delivery catheter is pulled back to release the self-expanding stent. **E**, Final angiogram.

FIGURE 60-5 Treatment of a perforated external iliac artery with a covered stent. **A**, Perforation (arrow) after directional atherectomy shown enlarged in the lower right-hand box. **B**, Deployment of a balloon-expandable covered stent. **C**, Final angiogram with the perforation sealed.

venous disease. Thrombolysis may be indicated for acute thrombosis with a threatened but viable extremity, but an immediately threatened limb (e.g., with sensory or early motor deficits) should be treated by surgical embolectomy, which offers more rapid reperfusion. Much of the experience with catheter-based thrombolysis is derived from its use for acute limb ischemia, venous thrombosis, or pulmonary embolism. It serves as an adjunctive treatment of semi-acute manifestations such as peripheral stent thrombosis. Long-term

results tend to be better when thrombolysis reveals an anatomic stenosis that probably precipitated the thrombosis and is treatable, for example, by repeated angioplasty.

Catheter-directed thrombolysis is more effective than intravenous thrombolysis only if an infusion catheter (with multiple infusion holes) is inserted into the thrombosed vessel. It is also less effective if given more than 14 days after thrombosis.^{3,4} Typically, the infusion is continued for 12 to 24 hours because treatment over a period of 48 hours is associated with depletion of circulating fibrinogen and a higher risk for major bleeding.²⁴ Catheter-based thrombolysis with or without angioplasty or stenting also reduces the incidence of post-thrombotic syndrome in patients with proximal (iliac) deep venous thrombosis,²⁵ and is used as adjunctive therapy for massive pulmonary emboli (see also Chapter 73).^{26,27}

There is a small risk for fatal or major bleeding with any thrombolysis regimen. Absolute contraindications to thrombolysis^{3,26} include (1) a cerebrovascular event less than 2 months previously, (2) active bleeding, (3) gastrointestinal bleeding less than 10 days previously, and (4) neurosurgery (intracranial or spinal surgery) or trauma less than 3 months previously. Relative contraindications include (1) cardiopulmonary resuscitation less than 10 days previously, (2) nonvascular surgery or trauma less than 10 days previously, (3) uncontrolled hypertension (sustained systolic

blood pressure >180 mm Hg or diastolic blood pressure >110 mm Hg), (4) puncture of a noncompressible vessel, (5) intracranial tumor, and (6) recent eye surgery.

Catheter aspiration thrombectomy uses catheters with a rapid-exchange port to direct the catheter to the thrombus and a large aspiration port to aspirate the catheter with a large syringe.^{3,4,26} These catheters can be used to aspirate smaller thrombi but are generally inadequate for a large burden of thrombus (e.g., long femoral stent thrombosis).

Mechanical thrombectomy includes a variety of devices that may include thrombolytic agents to help break up thrombus before suction by an aspiration catheter or catheters using the Venturi effect.^{3,4,26} Although mechanical thrombectomy is a more rapid treatment than catheter-directed thrombolysis, embolization can occlude the distal arterial bed and potentially lead to infarction and tissue loss.

Atherectomy and Other Treatments

Atherectomy devices, although conceptually attractive, have not proved better than angioplasty in direct comparisons in most arterial beds.^{12,28,29} Atherectomy is one of several niche tools and is most helpful in heavily calcified arteries to improve balloon and stent expansion or in regions where vessels are subjected to repetitive flexion or torsion, such as over joints, and where stents are avoided (because of kinking and increased fracture). In these settings, atherectomy may improve the distensibility of an artery to permit adequate expansion by balloon angioplasty without flow-limiting dissection. Drug-eluting balloons have renewed interest in this technology because they may reduce the contribution of excessive neointimal hyperplasia to restenosis. This strategy needs formal testing in clinical trials.

Coronary rotational atherectomy devices (Rotablator) are generally too small for the larger peripheral arteries, and it is uncertain how a large amount of plaque ablated from a long peripheral lesion would affect the downstream microcirculation (Fig. 60-6). Peripheral rotational atherectomy devices include the Jetstream, which has a 2.0-, 3.1-, and 3.5-mm cutting profile (Fig. 60-7), and the Diamond-back, which uses an eccentric location to achieve a larger cutting

arc.^{12,28,29} Directional atherectomy devices include the Silverhawk device (Fig. 60-8). All the peripheral devices have a tendency to embolize plaque into microvessels. Distal embolic protection devices may reduce this complication.

Cryoplasty involves the use of proprietary balloon and inflation technology to inflate the balloon with nitrous oxide, which chills on expansion to -10°C (Fig. 60-9). One pilot study suggested lower rates of restenosis in the femoral arteries when used with nitinol stents than when balloon angioplasty was performed,³⁰ but longer-term outcomes are uncertain.^{12,28,29}

PLANNING AN INTERVENTION

Vascular Imaging

Vascular imaging is the first stage of planning an endovascular intervention^{3,4} (Fig. 60-10). Traditionally, invasive angiography was used to determine the extent and severity of obstructive disease. Conventional angiography can use lower frame rates than needed for coronary angiography because most peripheral arteries are relatively static. Digital subtraction images remove bone and soft tissue from the image while leaving the contrast-enhanced image of the artery for more clarity, provided that the subtracted images remain still.

Noninvasive imaging is increasingly being used to plan vascular access and the tools probably required for the procedure. This includes magnetic resonance (MR) imaging using gadolinium or other contrast agents or time-of-flight techniques.³¹ Time-of-flight techniques rely on laminar blood flow and have the advantage of not requiring contrast material, which can rarely cause serious adverse effects (e.g., nephrogenic sclerosing fibrosis, see Chapter 17). But time-of-flight techniques may overestimate the severity of disease in regions of disturbed flow near obstructive or nonobstructive plaque. Computed tomography (CT) angiography using iodinated contrast material provides more rapid imaging, but heavy calcification can mask stenoses and make interpretation of lesion severity more difficult.^{32,33} Iodinated contrast agents can cause hypersensitivity and other allergic reactions or impair renal function.

MR imaging cannot be used in patients who have retained ferric metals (e.g., most pacemakers, shrapnel). Most stents are compatible with MR imaging but leave a flow void that does not allow

interpretation of obstructive disease. High-resolution contrast-enhanced CT scans can discern the patency of stents and are a better advanced imaging modality for assessing stent patency. Both MR imaging and CT tend to overestimate the severity of stenosis when compared with conventional invasive angiography.

Duplex ultrasound is very useful for imaging arteries in the limbs and the cervical arteries and veins. This modality does require considerable time to map out large arterial systems, however, hence the more common use of MR and CT angiography as noninvasive techniques to plan endovascular interventions.

Vascular Access

The most common vascular access for the lower limb is from the contralateral common femoral artery. A catheter is directed from the access side over the bifurcation of the aorta and into the target iliac arteries via a support wire. A sheath is directed up and over the aortic bifurcation and

pointed into the target iliac artery (**Fig. 60-11**). This approach is familiar to many operators and can be used to access the common femoral artery at its most superficial location. It also allows compression of the artery against the femoral head to aid in manual hemostasis after removal of the sheath.

The antegrade femoral approach involves skin access several centimeters cranial to the common femoral artery and angles toward the femoral head (see **Fig. 60-11**). This approach offers greater pushability for total occlusions and is closer to distal tibial lesions, but it is difficult in overweight patients, in whom the access needle must traverse a large distance through subcutaneous fat.

Rarely, retrograde access from the popliteal artery or from a tibial artery can assist in crossing a total occlusion that cannot be crossed from an antegrade approach³⁴⁻³⁶ (**Figs. 60-12 and 60-13**). The disadvantages of retrograde access are the potential to cause injury to

the distal access site because of the smaller artery size (tibial arteries) or more difficult hemostasis from a deeper location (popliteal). Techniques that combine retrograde and antegrade approaches can assist in crossing difficult total occlusions. An unsuccessful procedure from a retrograde access site, however, could lead to a nonhealing ulcer and critical limb ischemia, and for this reason it is generally used as a “last resort.”

Brachial artery access can permit access to the iliac arteries, but it is usually too far a distance from the superficial femoral arteries for most balloons and stent delivery devices. Upper limb lesions can be approached by a shuttle sheath from the femoral approach or by retrograde access from the radial or brachial approach. Brachial or radial artery access often provides better support for the mesenteric and renal arteries because these arteries typically angulate caudally.

ENDOVASCULAR TREATMENT OF ARTERIAL DISEASE

Peripheral Artery Disease of the Lower Extremities

The clinical history and physical examination can generally be used to differentiate PAD from other causes of leg discomfort. Physiologic tests such as the ABI (see Chapter 58) are quick and easy to perform, but segmental leg pressures can indicate the level of obstructive disease. Infrainguinal disease usually diminishes distal pulses and impairs the resting ABI. Typical symptoms of PAD with a normal resting ABI should raise suspicion for iliac or aortic disease, in which case an exercise ABI is generally abnormal (see Chapter 58). More advanced imaging such as MR, CT, or invasive angiography is generally indicated only if revascularization is being considered. MR imaging or CT can help identify the level, extent, and severity of PAD

and help indicate the likelihood of endovascular success versus surgical treatment, as well as access site and adjunctive endovascular technologies. In general, treatment of proximal disease offers higher long-term durability than does treatment of distal disease.

Aortoiliac Disease

Aortoiliac disease is approached from the ipsilateral femoral artery, contralateral femoral artery, or brachial artery. An ipsilateral femoral approach is more direct and associated with greater wire pushability through an occlusion. Many operators will often gain contralateral femoral access with a small sheath because this will provide quick access to the aorta or proximal iliac artery for temporary balloon occlusion in the event of perforation and rapid hemorrhage. Although plain balloon angioplasty produces a very durable result, balloon-expandable stents are now preferred for their better long-term durability, particularly with long lesions.^{3,4} “Kissing stents” are a well-described option for disease involving the distal aorta, but in

FIGURE 60-11 A-C, Access to a left iliac stenosis via the right common femoral artery. **A**, Access of the right femoral artery. The arrow indicates the access site of the femoral sheath. **B**, An Omniflush catheter is directed from the right iliac artery into the origin of the left iliac artery. **C**, A support wire is used to direct a sheath into the left common iliac artery for the intervention. **D**, Antegrade access of the common femoral artery with the tip of the sheath directed into the superficial femoral artery.

FIGURE 60-12 Antegrade and retrograde approach to a brachial artery stenosis. **A**, Unable to cross the stenosis from the antegrade approach with a shuttle sheath directed into the brachial artery from the femoral approach. **B**, Successful wire crossing retrogradely from the radial approach. many cases of iliac disease, landing stents at the ostium of the iliac artery yields a good response. Balloon-expandable stents are usually preferable for most lesions because of their greater radial strength and precision of placement, but self-expanding stents may be better in more tortuous lesions (Fig. 60-14). Although covered stents prevent plaque prolapse, their added value is uncertain and they have the potential disadvantage of occluding the opposite iliac artery if deployed too high or occluding the ipsilateral internal iliac artery if

deployed too low. They are useful for treating aneurysms and potentially lifesaving for treating vessel rupture or perforation.¹² Occlusions involving the distal aorta are generally treated surgically, although percutaneous transluminal angioplasty and stenting offer an option to patients with prohibitive surgical risk and critical limb ischemia.

The external iliac artery rises out of the pelvis and joins the common femoral artery just above the femoral head. This ascent out of the pelvis is deceptive on angiography, which may be related to

FIGURE 60-13 Anterograde and retrograde approach to an occluded below-knee popliteal and posterior tibial artery. **A**, Occluded segment (arrows). **B**, Retrograde wire from the posterior tibial artery accessed at the ankle. **C**, Anterograde and retrograde wires crossing the occlusion. **D**, The anterograde wire crossed the occlusion into the distal posterior tibial artery. **E**, Balloon angioplasty was followed by a short stent in the occluded segment. **F**, Final angiogram.

the higher risk for perforation or dissection with endovascular treatment. Once the artery leaves the pelvis, it can undergo external compression, in which case self-expanding stents should be considered. The technical success of endovascular angioplasty and stenting, particularly for shorter and common iliac lesions, is very good with excellent durability (>80% patency) over a 5-year period and is similar to that with surgical revascularization.^{3,12}

Femoral-Popliteal Artery Disease

Obstructive atherosclerosis is more common in the superficial femoral than the popliteal or common femoral arteries. Usually, the profunda femoris serves as an important source of collateral blood flow to the leg in patients with obstructive superficial femoral artery disease. The common femoral artery is more difficult to treat because it is subject to greater flexion and extension with movement of the hip, and complications that occlude this artery are likely to lead to an acute threatened limb as a result of obstruction of the profunda

and superficial femoral arteries. Even though balloon angioplasty can be used to successfully treat obstructive common femoral artery disease secondary to atherosclerosis or complications of common femoral access for other procedures, surgical repair with patch angioplasty is the standard of care for most patients with acceptable surgical risk. Balloon-expandable stents should not be used in this location because of repetitive compression during movement of the hip, and self-expanding stents should be avoided because of concerns of durability. The profunda femoris is a smaller artery with a thinner wall than the superficial femoral artery, and the risk for complications and evidence of long-term success with catheter-based intervention are uncertain.

Most percutaneous femoral interventions involve the superficial femoral and popliteal arteries, and interventional techniques are similar with both arteries. PAD commonly involves these arteries, which are subject to torsion and stretch with movement of the leg. The popliteal artery is particularly subject to torsion and kinking, and

FIGURE 60-15 The popliteal artery is subject to torsion and kinking on bending the knee. **A**, Popliteal angiogram in the anteroposterior view with the knee straight. **B**, Popliteal artery showing increased tortuosity in a rotated view with the knee flexed to 90 degrees. The arrows indicate the distal margin of a superficial femoral self-expanding stent.

stents are generally avoided below the level of the top of the patella and above the tibial metaphyseal plate when viewed with the leg straight (**Fig. 60-15**). Stenting between this region subjects stents to extreme flexion, compression, and torsion and is associated with stent fracture, restenosis, and poor long-term durability. As a result, stenting across the knee should be considered only in patients with critical limb ischemia and a poor angioplasty result and in those with prohibitive surgical risk.

Acute procedural success rates with catheter-based interventions now approach 90%, in part because of a wide variety of wires, crossing catheters, and reentry catheters for total occlusions. Restenosis rates are higher than in the iliac artery and may require repeated interventions. Catheter-based therapies should be considered part of a long-term strategy of surveillance for recurrent and new disease and repeated interventions when needed.^{37,38} Balloon angioplasty alone has durability similar to that of primary stenting for short lesions (<50 to 100 mm in length),³⁹ and in this setting, provisional stenting for abrupt closure, flow-limiting dissection, or poor expansion (residual stenosis >30% to 50%) is an acceptable strategy. For longer lesions (>100 mm), primary stenting with self-expanding nitinol stents may offer better durability and walking function than balloon angioplasty with provisional stenting can¹⁴ (**Fig. 60-16**; also see **Fig. 60-4** and **Videos 60-1** through **60-10**). Nitinol stents have lower restenosis rates than stainless steel self-expanding stents do. Initial results from studies of drug-eluting nitinol self-expanding stents suggest less restenosis than with balloon angioplasty and bare metal nitinol stents,^{15,16} but longer-term outcomes are awaited.

Atherectomy (directional, rotational, or laser), cutting balloons, and cryotherapy offer little routine advantage despite their theoretical value.^{14,28} Atherectomy may, however, permit greater luminal expansion with balloons and stents in calcified disease. Emboli occur in some cases with atherectomy, and many operators recommend embolic protection devices. There are no randomized direct comparisons of adjunctive techniques to balloon angioplasty or stenting in the femoral artery, but based on the evidence available and extrapolation from the coronary experience, their routine use does not reduce long-term risks for restenosis. Drug-eluting balloons offer lower restenosis rates than balloon angioplasty does^{19,20,22,23} and may

FIGURE 60-16 Composite angiograms showing a long occlusion of the right superficial femoral artery (arrow and dashed line in **A**). **B**, Three nitinol self-expanding stents were deployed in the superficial femoral artery to restore flow in this artery.

provide a durable result with or without atherectomy in regions where stents should be avoided, such as over joints.

Interventionalists need to establish systems to monitor patients for recurrent or new disease and treat atherosclerosis risk factors intensively. Collaboration with surgical colleagues and vascular medicine specialists should improve outcomes, although this conjecture has not undergone formal testing.

Tibial Disease

The popliteal artery divides into three tibial arteries: the anterior tibial, which becomes the dorsalis pedis in the foot; the posterior tibial, which forms the pedal arcade with the anterior tibial artery; and the peroneal artery, which usually ends just above the ankle but can be an important collateral to the foot. In general, claudication is rare with loss of even two of the three tibial arteries. Catheter-based interventions have high rates of restenosis, in part because of the small diameter and long lesion length, and are rarely justified in patients with claudication. Frequently, correction of obstructive proximal disease will resolve the claudication even when extensive tibial disease is left untreated.

In contrast, treating severe tibial disease in patients with critical limb ischemia can promote wound healing, resolve pain at rest, and prevent major amputation (**Fig. 60-17**). Multiple catheter-based interventions over a period of several months may be required to heal an ulcer if restenosis slows healing. Once healed, however, restenosis may be less of an issue, provided that adequate foot care and protection are used to prevent skin breakdown. Managing critical limb ischemia with ulceration or gangrene requires close follow-up to

AT = anterior tibial artery; P = peroneal artery.

débride dead tissue in ulcerated areas and aid healing. Gangrenous toes can usually be left dry until they mummify and autoamputate. Infected gangrene does require surgical amputation to avoid osteomyelitis. A team approach to care that includes wound specialists, podiatrists, surgeons, and prosthesis specialists is generally required.

Tibial disease is most often treated by prolonged balloon inflation, but stents are used as bail-out treatment of flow-limiting dissection¹² (Fig. 60-18; also see Fig. 60-13). Although balloon-expandable drug-eluting stents are used, they are prone to external compression, and drug-eluting balloons may offer greater durability.²¹

Cervical Artery Disease

Extracranial Carotid Disease

Extracranial disease of the internal and common carotid artery is a potential source of artery-to-artery embolism, one of the causes of ischemic stroke (see also Chapter 59). Over the last two decades, improvements in catheter-based techniques have enabled patients at increased risk for stroke from this cause to be treated with outcomes similar to those of traditional carotid endarterectomy.⁷

Symptoms are the most important factor related to the risk for disabling stroke and the indication for revascularization. Symptomatic disease refers to patients with a minor stroke or a transient ischemic attack. In the carotid circulation, symptoms are typically

dysphasia, contralateral hemiparesis or hemiparesthesia, or ipsilateral transient monocular blindness (amaurosis fugax).⁴⁰ Symptoms lasting less than 24 hours and without infarction noted on imaging are classified as transient ischemic attacks. Minor strokes are classified as mild clinical deficits or no clinical residual deficits with evidence of infarction on imaging.⁴⁰ The higher sensitivity of newer imaging techniques (e.g., diffusion-weighted MR imaging) compared with older technologies may have increased the likelihood of finding small infarcts with no residual clinical deficits.⁴⁰

The second factor related to stroke risk is the severity of stenosis of the extracranial internal carotid artery. For patients with recent symptoms and stenosis greater than 70%, the risk for stroke over the subsequent 5 years is up to 30%, with a risk of approximately 10% within the first 3 months.^{7,40} After 3 months, however, the risk for stroke declines and approaches the risk in asymptomatic patients with a similar degree of stenosis ($\approx 2\%$ to 3% per year).⁴¹

Carotid endarterectomy and stenting both entail a small procedural/operative risk for stroke, and this limits their benefit to patients at low risk for perioperative events but at higher risk for stroke in the long term without revascularization (Tables 60-1 and 60-2). Based on trials of surgery versus medical therapy from 20 years previously, carotid endarterectomy is recommended for symptomatic patients with greater than 50% to 99% stenosis by invasive angiography or greater than 70% stenosis by noninvasive imaging and with a periprocedural risk for stroke and death of less than 6%.^{7,40} For asymptomatic patients, indications include 80% to 99% stenosis in those with a periprocedural risk for stroke or death of less than 3%.⁷

Carotid stenting with embolic protection has evolved as a treatment that is equivalent to surgical carotid endarterectomy based on direct comparisons in randomized trials of patients with high and average risk for periprocedural cardiovascular events from surgery.^{42,43} Acceptably low periprocedural risk depends on adequate training of operators.⁴⁴ Randomized trials without certification of adequate carotid stent training tended to show higher periprocedural adverse events with stenting than with surgery,^{45,46} although after several years even these trials showed no difference in stroke or death.^{47,48} Potential indications for carotid stenting are the same as those listed earlier for endarterectomy. As with endarterectomy, several factors determine the success of carotid stenting. In addition to adequate operator training and experience, selection of patients at low risk for complications from carotid stenting is necessary. Patient selection is very important in asymptomatic patients or those several months after symptoms, in whom the absolute benefit from surgical endarterectomy or stenting is lower than in recently symptomatic patients.⁴⁴

In asymptomatic patients, the reduction in risk with revascularization is achieved slowly over the long term and needs to offset the small but important periprocedural/operative risk. This benefit usually takes several years to accrue, and asymptomatic patients need to have reasonable 5-year survival to have a realistic chance of achieving a net benefit from revascularization. Patients with a low risk for periprocedural stroke, myocardial infarction, or death are also selected so that the net long-term benefit is maximized. For carotid stenting this includes patients without severe vessel tortuosity, heavy calcification, or significant cognitive deficits.⁴⁴ Patients older than 80 years of age have a higher risk for perioperative adverse events with stenting or surgery.⁴⁴ The primary outcome of the recent CREST study of patients at average surgical risk suggested no difference in long-term outcomes between stenting and surgery.⁴² Secondary analyses suggested a slightly higher risk for periprocedural stroke with stenting (particularly in those older than 80 years of age) and a slightly higher risk for myocardial infarction with surgery.⁴²

Carotid stenting starts with access to the common carotid artery with a diagnostic catheter and then a delivery sheath. Embolic protection consists of distal protection using filters or obstructive balloons deployed distal to the carotid stenosis or proximal occlusion devices deployed proximal to the stenosis. Filters allow blood flow to the brain to continue and theoretically lead to less brain ischemia if the circle of Willis is incomplete. Self-expanding stents using delivery systems on a 0.014-inch platform are used to resist external compression (Figs. 60-19 and 60-20).

FIGURE 60-18 Bail-out stenting in a patient with critical limb ischemia and gangrene of the toes. **A**, Wire traversing an occluded peroneal artery. The anterior tibial and posterior tibial arteries were occluded. **B**, Balloon angioplasty of the peroneal artery. **C**, Dissection and recoil of the proximal peroneal artery. **D**, Stent deployment. **E**, Final angiogram of the peroneal artery.

TABLE 60-1 Factors Associated with Increased Risk for Complications with Carotid Artery Stent Placement

Tortuous aortic arch
Platelet or clotting disorder
Difficult vascular access
Lesion or vessel calcification
Visible thrombus
Advanced age (>75-80 yr)*

*The risk for a cerebrovascular accident with carotid artery stent placement is increased and the risk for myocardial infarction with carotid endarterectomy is increased.

TABLE 60-2 Factors Associated with Increased Risk from Carotid Artery Surgery

Anatomic Criteria
High cervical or intrathoracic lesion
Previous neck surgery or radiation therapy
Contralateral carotid artery occlusion
Previous ipsilateral carotid endarterectomy
Contralateral laryngeal nerve palsy
Tracheostomy
Medical Comorbidities
Age >80 yr*
Class III or IV congestive heart failure
Class III or IV angina pectoris
Left main coronary disease
Two- or three-vessel coronary artery disease
Need for open heart surgery
Ejection fraction ≤30%
Recent myocardial infarction
Severe chronic obstructive lung disease

*The risk for a cerebrovascular accident with carotid artery stent placement is increased, and the risk for myocardial infarction with carotid endarterectomy is increased.

Vertebral and Subclavian Disease

The left and right vertebral arteries usually arise from the left and right subclavian arteries, course through the upper vertebrae into the posterior of the skull, and join together as the basilar artery. One vertebral artery is often larger (dominant) than the other, and loss of one such artery is usually well tolerated. Vertebrobasilar insufficiency is a clinical diagnosis with symptoms affecting the brainstem and cerebellum, including dizziness, ataxia, diplopia, and syncope.⁴⁰ Atherosclerosis usually affects the proximal vertebral arteries, but vertebrobasilar insufficiency can be caused by more extensive proximal disease in the subclavian or brachiocephalic arteries. Patients with vertebrobasilar insufficiency have a 5-year risk for stroke of approximately 30% without any treatment.

Medical treatment of vertebral artery disease includes antiplatelet agents and 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors. Blood pressure control to reduce ischemic stroke requires careful titration to avoid hypotension and hypoperfusion, which can precipitate symptoms. Surgical therapy consisting of transection and reimplantation into an adjacent subclavian artery is associated with high morbidity, including Horner syndrome (2%), lymphocele (10% to 15%), chylothorax (<1%), and thrombosis (5% to 10%), as well as high mortality (5%). Extracranial percutaneous treatment, particularly with stenting, has much lower morbidity and short-term mortality, and long-term mortality is similar to that with surgery (10% to 20% at 3 years), partly related to the high prevalence of other comorbid conditions.⁴⁹

Subclavian stenosis more often affects the left subclavian origin than the brachiocephalic or right subclavian arteries. This predilection may result from more disturbed blood flow at the origin of the left subclavian artery. Subclavian stenosis usually causes a 15-mm Hg or greater difference in noninvasive brachial blood pressure between the two arms,⁵⁰ unless significant disease is present bilaterally. Most subclavian stenosis, however, is asymptomatic and does not need investigation or revascularization. Symptoms from subclavian stenosis include arm claudication with activity, angina in patients with a left internal mammary/thoracic artery graft from previous coronary artery bypass surgery⁵¹ (Fig. 60-21), vertebrobasilar insufficiency

FIGURE 60-19 Carotid stenting for symptomatic carotid stenosis. **A**, Stenosis at the origin of the left internal carotid artery. **B**, Stent deployed. Arrows indicate markers of the embolic protection filter. **C**, Final angiogram with arrows indicating the margins of the stent.

FIGURE 60-20 Intracranial angiograms from the patient in Figure 60-19. **A**, Right carotid angiogram showing the right internal carotid artery (IC), middle cerebral artery (MC), and anterior cerebral artery (AC). There is crossover filling through the anterior communicating artery into the left anterior cerebral artery because of poor left-sided perfusion from the left cervical internal carotid stenosis (Fig. 60-19A). **B**, Left carotid angiogram showing poor filling of the left AC relative to the MC. **C**, Improved perfusion of the left AC after stenting the left internal carotid artery (see Fig. 60-19D).

FIGURE 60-21 Stenting a left subclavian stenosis in a patient with angina and ischemia of the anterior left ventricular wall noted on stress testing. **A**, Shuttle sheath placed at the origin of the subclavian artery and stenosis. IMA = internal mammary artery; Vert = vertebral artery. **B**, Stent deployed to improve blood flow to the IMA.

with arm activity because of vertebral steal, or ischemic (hand) steal syndrome in patients with a dialysis fistula.⁵² Although noninvasive imaging can identify reverse flow in the vertebral artery distal to a subclavian stenosis, this physiologic abnormality does not always lead to symptoms, particularly if it involves a nondominant vertebral artery or blood flow in the contralateral vertebral artery is not impeded. Thus physiologic reversal of flow in the vertebral artery without symptoms is not an indication for revascularization.

Medical therapy targets the progression of atherosclerosis (e.g., antiplatelet agents, HMG-CoA reductase inhibitors, blood pressure control). Because most subclavian disease is proximal or ostial, surgical revascularization most commonly involves subclavian-to-common carotid bypass, a procedure associated with a 5% risk for morbidity, including stroke. For this reason, percutaneous revascularization with stents is more commonly used to revascularize symptomatic subclavian disease. Balloon-expandable stents are generally used because they allow more precise placement to cover the ostium of the artery and avoid the vertebral and left internal mammary artery origins. In the event that these distal branches are covered by “snowplowing” of plaque into the branch vessel, balloon-expandable stents permit dilation through the stent struts into the branch vessel. Embolic stroke is rare, possibly because of reverse flow down the vertebral artery during balloon dilation and stenting. Thus embolic protection is infrequently used for vertebral and subclavian artery stenting. The long-term results of stenting subclavian and brachiocephalic disease are excellent (>90% overall patency).⁵³

Mesenteric and Renal Artery Disease

Mesenteric Artery

Three arteries supply the mesenteric viscera: the celiac artery, superior mesenteric artery, and inferior mesenteric artery. Although advanced atherosclerosis of the aorta is common, mesenteric angina or infarction is very uncommon, probably because of the multiple

collateral networks in the mesentery. Acute mesenteric ischemia with infarction is a surgical emergency because it is usually associated with infarction of the small or large intestine.⁸ An embolus (e.g., from mural thrombus in the heart associated with atrial fibrillation) is a common cause and typically lodges in the proximal mesenteric artery (usually the superior mesenteric artery). Urgent surgery within 24 hours is required to resect dead bowel and revascularize ischemic bowel, with death in virtually all cases when diagnosis is delayed beyond this time.

Chronic mesenteric ischemia is a more insidious syndrome that causes discomfort or frank abdominal pain on eating and substantial weight loss because of food avoidance.⁸ Classically, more than two mesenteric arteries are stenosed or occluded. The disease is usually adjacent and involves advanced atherosclerosis of the aorta and origins of the mesenteric arteries. Asymptomatic disease of the mesenteric arteries does not require revascularization.

Endoscopy can be used to detect changes associated with ischemia, but noninvasive imaging with duplex ultrasound or MR or CT angiography generally identifies the extent of disease. Invasive angiography usually requires a lateral aortogram to clearly identify the origins of the mesenteric arteries. Surgical revascularization with reimplantation of the arteries has high mortality and morbidity (10% to 15%) because of the advanced age and other vascular comorbid conditions of patients. Percutaneous angioplasty with stenting has lower mortality (<5%) and morbidity and achieves good resolution of symptoms in about 70% to 80% of patients over a period of several years⁸ (Fig. 60-22). Restenosis may require further intervention and can be identified by duplex ultrasound and CT or MR angiography.

Renal Artery

Renal artery stenosis can cause secondary hypertension or rapidly deteriorating renal function. Clinical clues to the diagnosis of renal artery stenosis include onset of hypertension before 55 years of age, resistant or malignant hypertension (particularly in a previously

FIGURE 60-22 Mesenteric stenosis. **A, B**, Both these vessels proved to be critically stenosed. SMA = superior mesenteric artery. **C**, They were treated interventionally to restore wide patency in both, as outlined in **D**. The patient's symptoms abated and she began to gain weight.

TABLE 60-3 Clinical Predictors of Renal Artery Stenosis

1. Onset of hypertension in patients ≤ 30 yr or > 55 yr
2. Malignant, accelerated, or resistant hypertension
3. Unexplained renal dysfunction
4. Development of azotemia or worsening renal function after treatment with an angiotensin-converting enzyme inhibitor or angiotensin receptor blocker
5. "Flash" pulmonary edema
6. Atrophic kidney or > 1.5 -cm size discrepancy between kidneys
7. Multivessel coronary disease or peripheral arterial disease

Modified from Hirsch AT, Haskal ZJ, Hertzler NR, et al: ACC/AHA 2005 guidelines for the management of patients with peripheral arterial disease (lower extremity, renal, mesenteric, and abdominal aortic): Executive summary: A collaborative report from the American Association for Vascular Surgery/Society for Vascular Surgery, Society for Cardiovascular Angiography and Interventions, Society for Vascular Medicine and Biology, Society of Interventional Radiology, and the ACC/AHA Task Force on Practice Guidelines (Writing Committee to Develop Guidelines for the Management of Patients with Peripheral Arterial Disease) endorsed by the American Association of Cardiovascular and Pulmonary Rehabilitation; National Heart, Lung and Blood Institute; Society for Vascular Nursing; TransAtlantic Inter-Society Consensus; and Vascular Disease Foundation. *J Am Coll Cardiol* 47:1239, 2006.

well-controlled patient), rapidly increasing creatinine level over a several-month period or earlier, and sudden pulmonary edema without a clear cardiac cause (e.g., because of sudden hypertension with or without acute mitral regurgitation) (Table 60-3). Imaging with duplex ultrasound or with MR, CT, or invasive angiography can identify renal artery stenosis.

Resistant hypertension despite multiple antihypertensive agents is a marker of elevated cardiovascular risk,⁵⁴ and renal artery stenosis by itself does not correlate well with improved blood pressure after renal artery stenting. Renal artery sympathetic denervation is a promising endovascular technology for resistant hypertension⁵⁵ but is still under investigation.⁵⁶ (See Chapters 43 and 44)

Although renal artery stenosis is relatively common, determining whether it is a reversible cause of hypertension or declining renal function is difficult.⁹ Screening outside the aforementioned clinical scenarios is probably low yield and not justified because treatment does usually not have an impact on blood pressure control or renal function.⁵⁷ Recent randomized trials of stenting renal arteries with greater than 50% stenosis by angiography to control resistant hypertension or preserve renal function do not support intervention outside the clinical scenarios noted above.^{58,59} Many criticize these studies, however, because they included patients with hemodynamically insignificant disease.^{9,60} More strict angiographic criteria (e.g., $> 80\%$ stenosis) or stenosis with a translesional gradient using a small catheter (< 5 French [5F]) or pressure wire may identify lesions more likely to respond to renal artery stenting⁶⁰ (Fig. 60-23). Current catheter-based hemodynamic criteria at rest include a systolic gradient of at least 20 mm Hg or a mean gradient of at least 10 mm Hg. This approach was tested in the CORAL (Cardiovascular Outcomes in Renal Atherosclerotic Lesions) trial to see whether renal artery stenting improves renal function, blood pressure, or other clinical outcomes in patients identified by this approach. CORAL showed that renal artery stenting did not significantly add to prevention of clinical events beyond intensive medical therapy in patients with atherosclerotic renal-artery stenosis and hypertension or chronic kidney disease.⁶¹

Restenosis after renal stenting depends on the size of the artery, with larger arteries (diameter ≥ 6 mm) having lower restenosis rates than smaller-diameter arteries. Most

restenosis occurs in the first year, and long-term freedom from restenosis occurs in 80% to 90% of stented arteries.^{62,63} The clinical response to stenting is unpredictable, partly related to other comorbid conditions that affect renal function and blood pressure control, such as diabetic or hypertensive nephropathy. Markers proposed to indicate the likelihood of a clinical response to renal artery stenting include the clinical scenarios mentioned earlier, high translesional gradient with vasodilators (analogous to coronary fractional flow reserve), elevated brain natriuretic peptide, and a high resistive index (ratio of [peak systolic – end diastolic velocity]/peak systolic velocity) measured in the segmental arteries by duplex ultrasound. Yet more recent studies do not support the value of brain natriuretic peptide⁶² or the resistive index⁶⁴ as indicators of blood pressure response.

Although some patients with renal impairment and significant stenosis may see an improvement in renal function with stenting, approximately a third of patients see no improvement and in another 20% to 30% of patients renal function worsens, possibly because of atheroembolization. Even though many operators use embolic protection devices during renal stenting, their value in preventing atheroemboli or worsening renal function is unknown.

Fibromuscular dysplasia is a rarer cause of hypertension and often occurs in younger patients, with a higher prevalence in women.⁶⁵ Although defined histologically in the past, a recent classification based on imaging (multifocal "beading" versus unifocal) disease has some prognostic value.⁶⁶ Fibromuscular dysplasia typically involves the mid or distal renal artery, whereas atherosclerosis usually involves the ostium or proximal renal artery.⁹ Fibromuscular dysplasia is often accompanied by similar disease in other arterial beds (e.g., carotid arteries).⁶⁵ This diagnosis has particular importance in that balloon angioplasty without stenting often very effectively controls blood pressure with a durable response.

ENDOVASCULAR TREATMENT OF VENOUS DISEASE

Extremity Deep Venous Thrombosis

Upper and lower extremity deep venous thrombosis results from multiple factors often encompassed in the Virchow triad

FIGURE 60-23 Left renal artery stent for resistant hypertension and a 20-mm Hg gradient across the proximal stenosis using a pressure wire. **A**, Left renogram showing the ostial stenosis (short arrow) and filter embolic protection device (long arrow). **B**, Stent deployment with some overhang into the aorta. **C**, **D**, Early- and late-phase final angiogram.

(abnormalities in coagulation, hemodynamic flow, or endothelial injury) (see Chapter 73). Such factors include hypercoagulable states, venous stasis, external obstruction, scarring or congenital abnormalities of veins, or injury to veins. An important clinical distinction is whether the deep venous thrombosis is associated with an obvious reversible cause (provoked) or without an obvious cause (unprovoked and requiring longer anticoagulation.)

Lower extremity deep venous thrombosis is treated primarily medically with anticoagulation, but endovascular treatment is an option for patients with proximal venous thrombosis defined as being at the level of the common femoral vein or higher. Thrombosis at this site occurs in about a third of all cases of lower extremity deep venous thrombosis²⁶ and obstructs venous return from the lower limb. Proximal deep venous thrombosis occurs more frequently in the left leg as a result of compression of the left iliac vein by the overlying right

iliac artery (May-Thurner syndrome). Acute severe proximal deep venous occlusion, characterized by a blue limb, pain, and limb ischemia (phlegmasia cerulea dolens) is often associated with malignancy. Chronic post-thrombotic syndrome occurs over a period of several years in about half the cases of iliofemoral deep venous thrombosis²⁵ and is characterized by limb swelling, heaviness, and pain. Medical treatment includes compression stockings and anticoagulation. Endovascular treatment of proximal deep venous thrombosis via catheter-directed thrombolysis with or without balloon angioplasty and self-expanding stents reduces the incidence of post-thrombotic syndrome by about 20%²⁵ (Fig. 60-24).

Upper extremity deep venous thrombosis is related to effort-related proximal vein thrombosis in athletes (Paget-Schroetter syndrome), venous thoracic outlet syndrome, catheter-related thrombosis, or malignancy.⁶⁷ Effort-related thrombosis is usually associated with vigorous arm exercise (e.g., weightlifting).

Venous thoracic outlet syndrome is related to compression of the subclavian vein as it exits the thoracic cage between the clavicle, first rib, costoclavicular ligament, and subclavian and anterior scalene muscles. Catheter-related thrombosis is associated with indwelling catheters, ports, and pacemaker or defibrillator leads. Malignancy with external obstruction is more commonly associated with superior vena cava syndrome (see the next section). Anticoagulation is the most common treatment of upper extremity deep venous thrombosis, but endovascular therapy can provide relief from post-thrombotic syndrome. Endovascular therapy includes catheter-directed thrombolysis and treatment of any precipitating cause. For example, thoracic outlet syndrome generally requires surgical decompression (resection of the first rib or other structures) and venoplasty soon after thrombolysis because stents are subject to crushing and fracture in this location. Central venous catheters should be removed if

FIGURE 60-24 Venogram and intervention. A venogram of the left femoral vein was obtained after gaining access to the popliteal vein under ultrasound guidance. The patient is lying face down on the table to allow access to the popliteal vein. **A**, Baseline showing occlusion of the left femoral vein. **B**, Multihole catheter across the venous occlusion; administration of lytic agents is started. **C**, Four hours after lysis following percutaneous transluminal angioplasty and placement of a self-expanding stent to restore patency.

FIGURE 60-25 Superior vena cava (SVC) syndrome secondary to external compression of the SVC by a lung tumor and thrombosis of the SVC. **A**, Initial venogram showing compression of the SVC and filling defects because of thrombus. RA = right atrium. **B**, Venogram after 24 hours of catheter-directed thrombolysis with resolution of the thrombus but residual stenosis. **C**, Balloon venoplasty. **D**, Final angiogram after deployment of a self-expanding stent.

they are no longer required, or the patient should be kept on a long-term anticoagulation regimen.

Superior Vena Cava Syndrome

Superior vena cava syndrome results from obstruction of the superior vena cava with impairment of venous return from the head and upper limbs (see also Chapter 69). Typical causes include external compression, invasion from a tumor, or thrombosis related to an indwelling central catheter (e.g., for chemotherapy) or leads from pacemakers or defibrillators.⁶⁸ Symptoms include swelling and fullness in the head, headache, dyspnea, and a sense of choking. Angioplasty alone rarely relieves this condition successfully because of vessel recoil, but stenting very effectively reduces symptoms. Thrombosis of a stenosis is often present and requires catheter-directed thrombolytic therapy before balloon and stent therapy (Fig. 60-25). The stent usually needs to be oversized and extended well above and partly below the lesion so that it remains anchored and less likely to embolize. Anticoagulation is generally prescribed, often indefinitely for superior vena cava obstruction or thrombosis associated with malignancy. Symptoms usually respond rapidly within 24 hours. Ideally, indwelling catheters and pacemaker leads should be removed before stenting and reimplanted afterward if required. Long-term outcomes depend more on the cause of the superior vena cava obstruction, but in nonmalignant cases, high patency rates (>80%) over several years prevail.^{69,70}

SUMMARY AND FUTURE PERSPECTIVES, 1384**REFERENCES, 1385****GUIDELINES, 1386****SCOPE OF THE PROBLEM****Diabetes Mellitus**

Diabetes mellitus is a group of diseases characterized by insufficient production of insulin or by the failure to respond appropriately to insulin, resulting in hyperglycemia. The diagnostic criteria are summarized in **Table 61-1**.¹ Diabetes typically is classified as either type 2 diabetes, characterized by insulin resistance and relative insulin deficiency, representing greater than 90% of all diabetes cases, or type 1 diabetes, characterized by absolute insulin deficiency. In view of the excess and increasing prevalence of type 2 diabetes and its incremental cardiovascular risk compared with type 1 diabetes, the focus of this chapter is on type 2 diabetes, except when specifically indicated otherwise.

Diabetes is among the most common chronic diseases in the world, affecting an estimated 285 million adults in 2010 (6.4% of the global adult population).² The mounting incidence and prevalence of type 2 diabetes, driven by increasing population age, obesity, and physical inactivity, compound this high global burden (see **Chapters 1 and 42**), as does the increasing longevity of patients with diabetes. Estimates project that diabetes will affect more than 430 million persons (7.7% of the global adult population) by 2030² (**Fig. 61-1**).

Although much attention historically has focused on the prevention and treatment of microvascular disease complications of diabetes (i.e., retinopathy, nephropathy, and neuropathy), cardiovascular disease (CVD) remains the principal comorbid condition and primary contributor to mortality in the setting of diabetes—most commonly in the form of coronary heart disease (CHD), but also in the incremental risk associated with diabetes for cerebrovascular disease, peripheral vascular disease, and heart failure (HF). For these reasons, continuing efforts toward mitigating the risk of CVD in diabetes remain a global public health imperative.

Atherosclerosis

Compared with nondiabetic persons, patients with diabetes have a two- to fourfold increased risk for development of and death from CHD³ (**Fig. 61-2**). Although older studies have suggested a diabetes-associated CVD risk similar to that for nondiabetic patients with a previous myocardial infarction (MI), more recent observations from clinical trials including patients with diabetes suggest a substantially lower CHD risk, most likely reflecting the effectiveness of contemporary therapeutic interventions.⁴⁻⁶

Diabetes is associated with an increased risk for MI. Across the spectrum of acute coronary syndrome (ACS) events, in which diabetes may affect more than one in three patients,^{7,8} those with diabetes have worse CVD outcomes after ACS events⁹ (see **Chapters**

51 to 53). Despite overall improvements in outcomes during the past several decades for patients with and without diabetes, the gradient of risk associated with diabetes has persisted⁹ (**Fig. 61-3**), although the magnitude of incremental in-hospital mortality risk associated with diabetes after an ACS event has declined over the past decade⁸ (**Fig. 61-4**). Furthermore, the graded association of increased risk observed with diabetes in the setting of ACS extends to glucose values in the range well below the diabetes threshold, reflected by either glucose values at the time of presentation or those observed throughout hospitalization¹⁰ (**Fig. 61-5**).

In addition to CHD, diabetes increases the risks of stroke and of cerebrovascular and peripheral arterial disease. The diagnosis of diabetes portends a twofold increased stroke risk compared with nondiabetic persons (see **Chapter 59**). Hyperglycemia affects approximately one in three patients with acute stroke, and is associated with a two- to sixfold increased risk for adverse clinical outcomes after stroke.¹¹ Among patients with symptomatic peripheral arterial disease, diabetes prevalence ranges from 20% to 30% and accounts for approximately 50% of all lower-extremity amputations (see **Chapter 58**).¹²

Heart Failure

In the ambulatory setting, diabetes is independently associated with a two- to fivefold increased risk of HF over that in persons without diabetes, comprising both systolic and diastolic HF, and patients with diabetes have worse outcomes once HF has developed. In addition, diabetes associates with an increased HF risk in the setting of ACS events. The multiple factors that increase HF risk in diabetes include ischemic, metabolic, and functional myocardial perturbations.¹³

CORONARY HEART DISEASE IN THE PATIENT WITH DIABETES**Mechanistic Considerations Linking Diabetes and Atherosclerosis**

Traditional CHD risk factors such as hypertension, dyslipidemia, and adiposity cluster in patients with diabetes (see **Chapters 42 to 45**)—but this clustering does not completely account for the increased risk observed among patients with diabetes, with numerous other implicated mechanisms¹⁴ (**Table 61-2**).

The mechanisms by which hyperglycemia increases CVD risk remain poorly understood, but given the clear associations between the severity of hyperglycemia and CVD risk in both type 1 and type 2

TABLE 61-1 American Diabetes Association Diagnostic Criteria for Diabetes Mellitus

Fasting plasma glucose ≥ 7.0 mmol/liter (126 mg/dL)
or
2-hour plasma glucose ≥ 11.1 mmol/liter (200 mg/dL) during standardized 75-g oral glucose tolerance test
or
Symptoms of hyperglycemia plus nonfasting plasma glucose ≥ 11.1 mmol/liter (200 mg/dL)
or
HbA1c $\geq 6.5\%$

diabetes, it probably directly influences atherosclerosis development, progression, and instability.¹⁴ The principal vascular perturbations linked to hyperglycemia include endothelial vasomotor dysfunction, vascular effects of advanced glycation end products, adverse effects of circulating free fatty acids, and increased systemic inflammation. In addition, the pernicious effects of hypoglycemia complicating diabetes therapy, the sympathovagal imbalance due to diabetic autonomic neuropathy, and the vascular effects of constitutive exposure to excess insulin may further contribute to atherosclerotic risk.

Endothelial vasomotor dysfunction, a hallmark of diabetic vascular disease, is associated with increased hypertension and adverse CVD outcomes. The myriad mechanisms contributing to endothelial dysfunction include abnormal nitric oxide biology, increased endothelin and angiotensin II, and reduced prostacyclin (i.e., prostaglandin I₂) activity, all of which contribute to abnormal control of blood flow. In

the setting of ACS events, the no-reflow phenomenon after percutaneous intervention reflecting acute endothelial dysfunction occurs more commonly in the presence of hyperglycemia independent of diabetes status and may contribute to increased myocardial jeopardy, resulting in larger infarcts, increased arrhythmia, and worse systolic function.

Abnormalities in lipid metabolism also contribute to the increased atherosclerotic risk associated with diabetes (see Chapters 42 and 45). High triglyceride levels, low high-density lipoprotein (HDL) concentration, and increased atherogenic small dense low-density lipoprotein (LDL) particles characterize diabetic dyslipidemia, and each may contribute to the accelerated development and progression of atherosclerosis.

Perturbations in the coagulation and fibrinolytic pathways and in platelet biology add to the vascular risk of diabetes, yielding a constitutive prothrombotic milieu.¹⁵ These abnormalities include increased circulating tissue factor, factor VII, von Willebrand factor, and plasminogen activating inhibitor 1, with decreased levels of antithrombin III and protein C. In addition, disturbances of platelet activation, aggregation, morphology, and lifespan further contribute to increased thrombotic potential, as well as to the acceleration of atherosclerosis.

Increased systemic inflammation portends an increased risk for diabetes and diabetic atherosclerotic disease, and diabetes is associated with increased oxidative stress and the accumulation of advanced glycation end products. For example, diabetes is associated with lipid-rich atherosclerotic plaque and increased inflammatory cell content, increased expression of tissue factor, and increased expression of the receptor for advanced glycation end products, yielding plaques with characteristics of higher risk in both coronary and carotid arteries.¹⁴

Prevention of Coronary Heart Disease and Its Complications in the Setting of Diabetes

Therapeutic lifestyle interventions remain the cornerstone of prevention of the atherosclerotic complications associated with diabetes. As recommended by the American

Diabetes Association (ADA) and the American Heart Association (AHA), overarching therapeutic lifestyle targets include smoking abstinence, at least 150 minutes of moderate-intensity aerobic activity weekly, and nutrition recommendations for weight control and dietary composition.^{16,17} Although lifestyle modification may not affect cardiovascular outcomes when instituted in patients with established diabetes, such intervention reduces risk factors for vascular disease and yields many health benefits.^{18,19}

Beyond lifestyle, pharmacologic strategies effectively reduce CVD risk in diabetes.^{16,17,20} Such interventions include assiduous blood pressure and lipid management for all patients, and for patients at highest risk, angiotensin-converting enzyme (ACE) inhibitors independent of blood pressure and also daily aspirin.^{16,17} In the context of these evidence-based CVD interventions, the accumulated data regarding the effects of glucose control on CVD risk mitigation remain less robust.^{16,21,22}

Lipid-Lowering Therapy

Type 2 diabetes is associated with a characteristic pattern of dyslipidemia, reviewed in detail in [Chapter 45](#). Each component of the diabetic dyslipidemia profile is independently associated with CVD risk, including increased small, dense LDL particles, increased apolipoprotein B concentration, increased triglycerides, and decreased HDL cholesterol. Despite extensive research in modifying triglyceride and HDL cholesterol levels with a variety of pharmacologic agents, however, the net influence on CVD risk of these strategies remains uncertain, and statin treatment remains the cornerstone of therapeutic lipid intervention in patients with diabetes ([see also Chapter 42](#)).

Statins

Contemporary guidelines for the management of diabetic dyslipidemia focus on the use of statin medications,^{16,17,23} with meta-analyses of randomized clinical trials enrolling large numbers of patients with diabetes yielding estimates of numbers needed to treat to prevent one major adverse CVD complication over 5 years in the setting of diabetes: 39 for primary prevention and 19 among patients with prevalent CVD.²⁴

Recommendations from many contemporary professional societies do not require elevation of LDL cholesterol as a requisite for the initiation of a statin, advising such therapy in all patients with diabetes older than 40 years of age with one or more CVD factors, or younger in the setting of prevalent CVD, endorsing a target of LDL less than 100 mg/dL or 35% to 40% reduction from baseline.¹⁶ An optional, more intensive target has been endorsed for patients with diabetes of LDL cholesterol below 70 mg/dL and non-HDL cholesterol less than 100 mg/dL.¹⁷

The 2013 AHA/ACC Lipid Guideline advises statin treatment for people with diabetes between the ages of 40 and 75 years with LDL cholesterol levels between 70 and 189 mg/dL even if they have not had a prior cardiovascular event. This guideline does not recommend LDL target levels (see the Guideline section following Chapter 42).²³ The 2013 guideline suggests that in statin-intolerant patients a secondary option is to add another lipid-modifying agent such as ezetimibe, bile acid binders, fibric acid derivatives, fish oil, or niacin. The net CVD efficacy and overall safety associated with such add-on therapy, however, remain unsubstantiated.

The most recent guidelines from the AHA and the American College of Cardiology (ACC) endorse the prescription of statin drug and intensity predicated on estimated 10-year risk for atherosclerotic vascular disease,²³ independent of LDL cholesterol concentrations or specified LDL cholesterol or non-HDL cholesterol therapeutic targets. For patients with type 2 diabetes, at least moderate-intensity statin therapy is endorsed for all patients with diabetes exceeding 7.5% estimated 10-year risk for atherosclerotic cardiovascular complications. These guidelines also discourage add-on lipid-modifying therapies, reserving their use for patients intolerant of statins.

Intensive-dose versus moderate-dose statin therapy reduces cardiovascular risk further,²⁴ but a large meta-analysis and analyses of data from several randomized clinical trials have identified an increased risk of new-onset diabetes associated with intensive-dose statin therapies compared with placebo or standard care (reviewed in detail in [Chapter 42](#)).²⁵ These observations suggest a deleterious effect of intensive-dose statin therapy on glycemia, due to unknown mechanisms. Whether intensive-dose statin therapy adversely affects glucose control among patients with prevalent diabetes remains uncertain. In view of the potent favorable influence of statin therapy at reducing CVD risk, however, the observed incremental risk of incident diabetes should not discourage aggressive use of intensive-dose statin therapy in eligible patients with diabetes.

Omega-3 Fatty Acids

Inasmuch as omega-3 fatty acids ([see Chapters 45 and 46](#)) can reduce circulating triglycerides by up to 40%, such preparations—predominantly fish oil preparations in clinical use—hold particular promise in the treatment of diabetic dyslipidemia. In addition, in the absence of reported interactions with statins, fish oil is particularly

attractive as an add-on therapy to statins if incremental triglyceride reduction is desired once LDL cholesterol targets have been achieved with statin therapy. A series of randomized clinical trials have demonstrated beneficial effects on CVD outcomes with fish oil, such as data from a subanalysis of 4565 patients with impaired fasting glucose or diabetes participating in the Japan EPA Lipid Intervention Study (JELIS), a randomized trial comparing treatment with 1800 mg of eicosapentaenoic acid (EPA) plus simvastatin daily versus simvastatin alone.²⁶ In this subset, EPA treatment conferred a 22% risk reduction ($P = 0.048$) for major adverse CVD events compared with simvastatin alone. But subsequent results from the Outcome Reduction with an Initial Glargine Intervention (ORIGIN) randomized trial have challenged these findings. In ORIGIN, 12,536 patients with impaired fasting glucose, impaired glucose tolerance, or diabetes were randomly assigned to receive either a 1-g capsule containing at least 900 mg (90% or more) of ethyl esters of n-3 fatty acids or a capsule containing 1 g of olive oil daily.²⁷ The primary outcome was cardiovascular mortality. Over a median follow-up period of 6.2 years, no significant reduction in the primary outcome occurred with n-3 fatty acid treatment versus control (9.1% versus 9.3%, respectively; $P = 0.72$), with a total of 1155 total cardiovascular death events to analyze—yielding substantial statistical power. Of note, in contrast with the JELIS trial, the total dose of n-3 fatty acids used in the ORIGIN trial was significantly lower (1800 mg versus 900 mg, respectively); the fish oil formulation in ORIGIN contained a mixture of docosahexaenoic acid (DHA) (approximately 45%) and EPA, whereas the JELIS trial used a formulation of only EPA, and the comparator in ORIGIN was not a true placebo but a capsule containing 1 g of olive oil taken daily. The degree to which these contrasts contributed to the different observed results remains unclear. As indicated by the accumulated data, fish oil remains a reasonable adjunct to statin therapy in patients with diabetes or who have extremely high levels of triglycerides (>500 mg/dL), to mitigate hyperviscosity complications.

Fibric Acid Derivatives (Fibrates)

Fibrates are agonists of the nuclear transcriptional regulator peroxisome proliferator-activated receptor alpha (PPAR- α) that lower triglycerides and modestly increase HDL cholesterol. Although they favorably affect two of the fundamental abnormalities of diabetic dyslipidemia, the net CVD effects of this class of drugs remain uncertain. Randomized trials of gemfibrozil versus placebo have demonstrated efficacy in subjects with diabetes, but these trials were executed before the use of statins became prevalent in the populations studied, and an increased risk of myopathy limits the use of gemfibrozil with statins. Subsequently, the Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) trial evaluated the CVD effect of fenofibrate versus placebo in a population of 9795 patients with type 2 diabetes and showed no statistically significant reduction in the primary endpoint of coronary death or nonfatal MI, despite accumulating 544 primary outcome events for evaluation (5.2% versus 5.9%; hazard ratio [HR], 0.89 [95% confidence interval {CI}, 0.75 to 1.05]).²⁸ The prevalent drop-in of statin use in the placebo arm may have contributed to this negative result, but in the present era, when statins are indicated for all patients eligible for the FIELD trial, the trial results have limited generalizability and challenge the utility of fenofibrate add-on therapy for CVD risk mitigation. In the more recently completed ACCORD (Action to Control Cardiovascular Risk in Diabetes) lipid trial that included 5518 patients with type 2 diabetes at high cardiovascular risk, fenofibrate compared with placebo, each added to simvastatin background therapy, likewise failed to yield significant improvements in major adverse cardiovascular outcomes, despite the accumulation of 601 primary endpoint events of cardiovascular death, MI, and stroke.²⁹

Fibrates remain an option for patients with intolerance to statin medications, for isolated hypertriglyceridemia in diabetic patients at otherwise low CVD risk, and as add-on therapy to maximally tolerated statin monotherapy when patients do not achieve therapeutic targets (with the recognition of some increased myopathy risk).

Gemfibrozil should never be added to statin therapy because of an unacceptable risk of muscle complications. Although individual trials have failed to demonstrate conclusively a benefit of fibrates on CVD risk, a meta-analysis of the published data suggests modest but significant improvements in composite and component cardiovascular outcomes, with or without background statin therapy.³⁰ In addition, subanalyses of the reported trials suggest that patients with diabetes who have baseline high triglycerides concomitant with low HDL cholesterol may benefit from incremental CVD risk reduction with fibrates added to background therapy—a hypothesis pending confirmation in a dedicated randomized trial.

Niacin

Niacin is a potent modulator of lipid metabolism (although the mechanism of action remains poorly understood) and has the greatest effect among currently available drugs on increasing HDL-cholesterol while also lowering triglycerides. But the net CVD effects and safety of niacin, especially in the context of background statin therapy, remain undetermined. As with fibrates, the accumulated data set regarding the net CVD effects of niacin remains limited primarily by relatively small studies with substantial dropout rates; a recent meta-analysis estimated a 27% relative risk reduction associated with niacin in the absence of statin background therapy.

Two large-scale randomized trials recently evaluated the incremental CVD efficacy and safety of niacin added to statin therapy by comparing niacin formulations versus placebo, each added to background simvastatin therapy. In the National Institutes of Health (NIH)-sponsored Atherothrombosis Intervention in Metabolic Syndrome with Low HDL/High Triglycerides: Impact on Global Health Outcomes (AIM-HIGH) trial, 3414 patients with established atherosclerotic cardiovascular disease were randomly assigned to blinded treatment with extended-release niacin, 1500 to 2000 mg/day, or matching placebo, with a primary trial outcome of the first event of the composite of death from CHD, nonfatal MI, ischemic stroke, hospitalization for an ACS, or symptom-driven coronary or cerebral revascularization.³¹ All patients received simvastatin, 40 to 80 mg/day, plus ezetimibe 10 mg/day if needed, to maintain a LDL cholesterol level of 40 to 80 mg/dL. This trial was halted prematurely with a mean follow-up of 3 years due to futility of the intervention on the primary outcome for niacin versus placebo (16.4% versus 16.2%, respectively; $P = 0.79$), in the setting of a nonsignificant numeric excess for ischemic stroke in the niacin versus placebo arm (29 patients versus 18 patients; $P = 0.11$). Observations among the subset of 1158 patients enrolled with prevalent diabetes were similar to the overall trial results, with no statistical interaction observed.

The Heart Protection Study 2-Treatment of HDL to Reduce the Incidence of Vascular Events (HPS2-THRIVE) trial enrolled 25,673 patients with prevalent atherosclerotic vascular disease randomly assigned to blinded treatment with extended-release (ER) niacin/laropiprant combination tablet or placebo, both added to background simvastatin therapy with or without ezetimibe.³² The primary trial endpoint was time to the first event of a composite of coronary death, nonfatal MI, stroke, or coronary revascularization, with no significant difference observed between the groups randomized to ER niacin/laropiprant versus placebo (14.5% versus 15.0%; $P = 0.29$), although for the component endpoint of coronary revascularization, a statistically significant 11% reduction occurred with ER niacin/laropiprant versus placebo (4.6% vs. 5.2%; $P = 0.04$). The comparative efficacy in the subset of patients with prevalent diabetes at study entry ($n = 8299$ [32%]) conformed to the overall trial results, with an interaction P value of 0.98. Of considerable concern, the risk of adverse events increased significantly with ER niacin/laropiprant, including a statistically significant 3.7% absolute increased risk for hyperglycemic and hypoglycemic events among patients with diabetes, and a 1.8% absolute (27% relative) increased risk for incident diabetes with niacin/laropiprant (9.1% versus 7.3%) (HR, 1.27 [95% CI, 1.14 to 1.41]).

Like fibrates, niacin remains an option for patients with intolerance to statins, for isolated hypertriglyceridemia in diabetic patients with an otherwise low CVD risk, and as add-on therapy to maximally tolerated statin monotherapy, although the AIM-HIGH and HPS2-THRIVE

trial results challenge the latter application. Current data do not support niacin use as an add-on to statin therapy in patients achieving target LDL cholesterol levels.

Hypertension Management

Hypertension (see Chapter 44) affects approximately 70% of diabetic patients (twice the rate observed in nondiabetic subjects), with a steep graded association between blood pressure and adverse cardiovascular outcomes³³ (Fig. 61-6). In this context, numerous classes of antihypertensive medications reduce diabetic CVD risk,³⁴ and given the potent benefits for both macrovascular and microvascular disease complications, blood pressure management has great importance in this high-risk population. Furthermore, blood pressure targets for patients with diabetes are more aggressive than for the overall population, with a goal of less than 130/80 mm Hg for patients with diabetes who can tolerate such aggressive management without undue clinical burden, and a target of below 140/80 for all others.^{16,17}

Renin-Angiotensin-Aldosterone System Antagonists

ACE inhibitors and angiotensin II receptor blockers (ARBs) have become cornerstones of therapy for hypertension in diabetes because of their broadly demonstrated favorable effects on diabetic nephropathy and CVD outcomes, as well as their modest favorable effects on measures of glucose metabolism.^{16,17,34,35} These drugs are antagonists of the renin-angiotensin-aldosterone system (RAAS).

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS. Data from randomized trials of patients with and without hypertension support the recommendation for ACE inhibitors as first-line agents for treatment of hypertension in the setting of diabetes. For example, the Heart Outcomes Prevention Evaluation (HOPE),³⁶ which compared ramipril (10 mg daily) with placebo in patients at increased risk for CVD, ramipril was superior to placebo in the diabetes subset of 3577 HOPE patients for the primary outcome of cardiovascular death, MI, and stroke (25% relative risk reduction [RRR]; $P = 0.004$), and for overt nephropathy (24% RRR; $P = 0.027$). Similar observations derive from the diabetes subanalysis of the EUROPA (EUROpean trial On reduction of cardiac events with Perindopril in stable coronary Artery disease) trial,³⁷ which tested perindopril versus placebo; the point estimate of treatment effect with perindopril compared with placebo, a 19% relative risk reduction among the 1502 participants with diabetes, resembled the 20% risk reduction observed in the overall trial. On the basis of these results and support from a meta-analysis of data from reported trials,³⁴ ACE inhibitors are recognized as first-line agents for the treatment of hypertension in the setting of diabetes and should be considered for all diabetic patients with prevalent CVD or a clustering of CVD risk factors.^{16,17}

ANGIOTENSIN II RECEPTOR BLOCKERS. Cardiovascular outcomes data for ARBs are much less robust than for ACE inhibitors, particularly in patients with diabetes. The Telmisartan Randomized Assessment Study in ACE Intolerant subjects with cardiovascular Disease (TRANSCEND) trial enrolled 5926 patients with intolerance to ACE inhibitors, randomly assigned to receive telmisartan (80 mg daily) or placebo, including 2118 patients with diabetes.³⁸ In the overall trial, telmisartan failed to achieve statistical superiority over placebo in reducing the primary composite of CVD death, MI, stroke, and HF hospitalization (HR, 0.92 [95% CI, 0.81 to 1.05]), but it significantly reduced the secondary composite of cardiovascular death, MI, and stroke (HR, 0.87 [95% CI, 0.76 to 1.00]). Although subgroup analyses lacked statistical power, the point estimates of effect for both the primary and key secondary outcomes were markedly attenuated in the subset of patients with diabetes. Guidelines from the ADA and AHA have endorsed ARBs and ACE inhibitors with similar levels of recommendation,^{16,17} but with little evidence available regarding the effects of ARBs on CVD outcomes, ACE inhibitors should remain first-line agents, with ARBs reserved for patients who cannot tolerate ACE inhibitors because of cough, angioedema, or rash.

Calcium Channel Blockers

Dihydropyridine calcium channel blockers generally are well tolerated and effectively lower blood pressure. Analyses of data for

diabetes subsets in randomized clinical trials suggest a magnitude of CVD clinical benefit similar to or greater than that observed in nondiabetic cohorts, including evaluations of nitrendipine, nisoldipine, and amlodipine.³⁴ In active-controlled comparisons, amlodipine has shown superiority to hydrochlorothiazide when added to background benazepril therapy,³⁹ but in randomized trials directly comparing the efficacy of calcium channel blockers versus ACE inhibitors, ACE inhibitors provide superior outcomes.

Beta Blockers

Antagonists of beta-adrenergic receptors (beta blockers) are another key component of effective CVD risk reduction in diabetes. Early in the course of clinical use, beta blockers were judged to be relatively contraindicated in the setting of diabetes because of concerns about masking hypoglycemia symptoms and adverse effects on glucose and lipid metabolism. The results of CVD outcomes trials have allayed these concerns and support the benefit of beta blockers for patients with diabetes in the chronic ambulatory setting⁴⁰ and in the post-ACS population.⁴¹ In addition, the metabolic effects of various beta blockers may differ: With non-cardioselective beta blockers that also have alpha receptor-blocking properties, metabolic markers may improve, although the clinical relevance of these differential effects remains unproved. A meta-analysis of randomized clinical trials supports the utility of beta blockers in the treatment of patients with diabetes.³⁴

Thiazide Diuretics

Concern about the adverse glycemic and triglyceridemic effects of the thiazide diuretic class of medications—including hydrochlorothiazide, chlorthalidone, indapamide, and bendroflumethiazide—has resulted in some degree of hesitancy regarding use of these medications in diabetic patients. Of note, however, randomized trials of thiazide diuretics that included substantial numbers of patients with diabetes have consistently demonstrated CVD benefits. In a subanalysis of the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), the CVD effects of chlorthalidone compared with both lisinopril and amlodipine were similar in patients with diabetes or impaired fasting glucose, despite modest but statistically significant increases in incident diabetes associated with chlorthalidone use.⁴² A meta-analysis of randomized trials further supported the benefits of thiazide diuretics in the treatment of patients with diabetes.³⁴

Combination Therapy for Hypertension

In addition to demonstrating efficacy of individual drugs, studies also have proved the benefits of combination antihypertensive therapy in patients with diabetes. In the Action in Diabetes and Vascular disease: preterAx and diamicroN-MR Controlled Evaluation (ADVANCE) trial, which compared combination therapy with perindopril plus indapamide versus placebo in 11,140 patients with type 2 diabetes,⁴³ the combination therapy was associated with a 9% relative reduction in

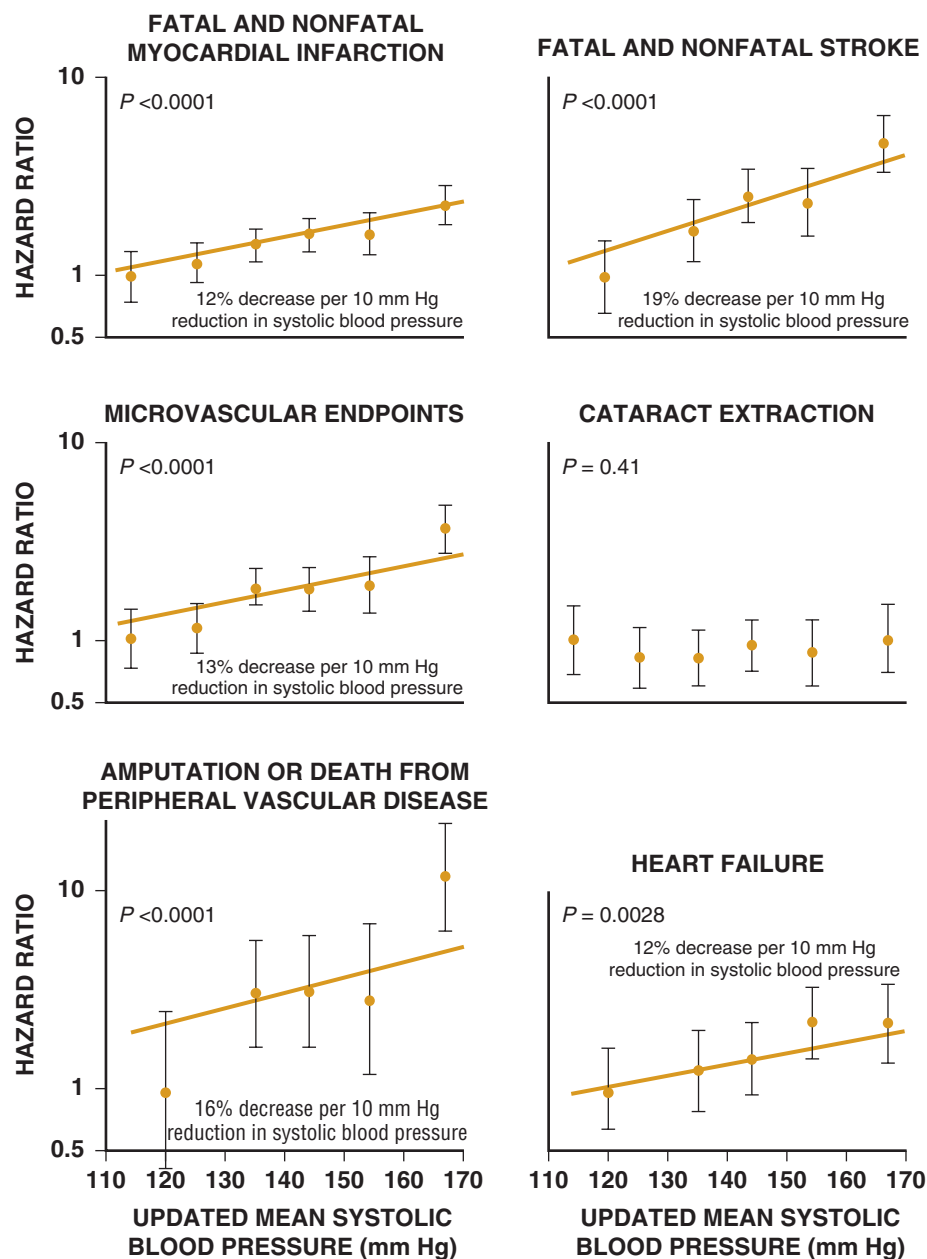

FIGURE 61-6 Hazard ratios (95% confidence intervals as floating absolute risks) as estimate of association between category of updated mean systolic blood pressure and MI, stroke, and HF, with log linear scales. Reference category (hazard ratio of 1.0) is systolic pressure less than 120 mm Hg for MI and less than 130 mm Hg for stroke and HF; P values reflect contribution of systolic pressure to multivariable model. Data adjusted for age at diagnosis of diabetes, ethnic group, smoking status, presence of albuminuria, HbA1c, HDL and LDL cholesterol, and triglyceride. (Modified from Adler AI, Stratton IM, Neil HA, et al: Association of systolic blood pressure with macrovascular and microvascular complications of type 2 diabetes (UKPDS 36): Prospective observational study. *BMJ* 321:412, 2000.)

a composite primary outcome combining microvascular and macrovascular disease endpoints, compared with placebo. In the Anglo-Scandinavian Cardiac Outcomes Trial–Blood Pressure Lowering Arm (ASCOT-BPLA),⁴⁴ which randomly assigned patients to treatment to amlodipine, with perindopril added as needed, or atenolol with bendroflumethiazide added as needed, the amlodipine-perindopril combination yielded a significant 13% relative risk reduction ($P = 0.028$) in major CVD outcomes in the 923 patients with diabetes, compared with atenolol-bendroflumethiazide. Finally, in the Avoiding Cardiovascular Events through Combination Therapy in Patients Living with Systolic Hypertension (ACCOMPLISH) trial,³⁹ in which all patients were treated with benazepril, with randomization to add-on amlodipine versus add-on hydrochlorothiazide, treatment with benazepril-amlodipine versus benazepril-hydrochlorothiazide was associated

with a 21% reduction in CVD outcomes among the 6946 patients with diabetes (60.4% of the study cohort; $P=0.003$). Therefore, in combination with thiazide diuretics and with amlodipine, ACE inhibitors are associated with improved CVD outcomes, with the combination with amlodipine proving superior in head-to-head comparison.

Blood Pressure Targets for Patients with Diabetes

In view of the increased CVD risk associated with hypertension in diabetes mellitus and the clearly demonstrated graded association between blood pressure reduction and CVD risk, observational data suggest that patients with diabetes mellitus constitute a special population requiring more aggressive blood pressure control (see also [Chapter 44](#) and the Guidelines section at the end of this chapter). Recent randomized clinical trials generally have supported this concept, including the National Heart, Lung and Blood Institute (NHLBI)-sponsored ACCORD trial, in which 4733 patients with type 2 diabetes at high cardiovascular risk were randomly assigned to treatment to achieve systolic pressure goals of either less than 120 mm Hg or less than 140 mm Hg.⁴⁵ In a comparison of the more intensive and less intensive arms, the point estimate of a 12% relative risk reduction in the primary composite endpoint of cardiovascular death, MI, and stroke failed to achieve statistical significance (HR, 0.88 [95% CI, 0.73 to 1.06]); more intensive control was associated with a significant 41% reduction in stroke (HR, 0.59 [95% CI, 0.39 to 0.89]). Of note, at the time of randomization, when clinical guidelines endorsed systolic blood pressure targets of less than 130/80 mm Hg, the average blood pressure at study entry was 139/76 mm Hg in this high-risk cohort. During the trial, the average systolic pressure achieved in the below 120 mm Hg arm was 119.3 mm Hg, contrasted with an average of 133.5 mm Hg in the patients randomly assigned to a target of below 140 mm Hg, requiring an average of 3.4 and 2.3 medications, respectively. Therefore, although the trial failed to prove the benefit of more intensive blood pressure control over contemporary targets, the pressures achieved in the less intensive group fell quite close to such targets, and in the context of favorable secondary outcomes with no prohibitive safety signals observed, the current target of below 130/80 mm Hg seems prudent for most patients with diabetes, with no clear imperative to achieve more aggressive control.

Bangalore and colleagues analyzed 13 randomized trials with 37,736 participants to evaluate target blood pressure goals for patients with type 2 diabetes, impaired fasting glucose (IPG), or glucose intolerance (IGT).⁴⁶ Intensive blood pressure control (with targeted values of ≤ 130 mm Hg systolic) was associated with a 10% reduction in all-cause mortality (odds ratio [OR], 0.90; $P < 0.05$), and a 17% reduction in stroke, compared with standard blood pressure control levels (≤ 140 mm Hg). It also was associated, however, with a 20% increase in serious adverse events, including a 17-fold increase in hypotension and a 10-fold increase in hyperkalemia. Intensive blood pressure control did not improve cardiac, renal, or retinal outcomes over those achieved with standard blood pressure control. Meta-regression analysis showed continued risk reduction for stroke with a systolic pressure of less than 120 mm Hg, but at levels below 130 mm Hg, serious adverse events increased by 40%, with no benefit seen for renal, retinal, or cardiac outcomes. The investigators concluded that based on the available body of evidence, a systolic pressure treatment goal of 130 to 135 mm Hg is acceptable. Although the risk of stroke continued to fall with more aggressive goals, the risk of treatment-related adverse events rose substantially, with no benefit regarding the risk of other macrovascular or microvascular events.

To explore further the epidemiologic relationships between intensity of blood pressure control achieved and cardiovascular outcomes, Redon and colleagues performed post hoc analyses of the Ongoing Telmisartan Alone and in Combination with Ramipril Global Endpoint Trial (ONTARGET).⁴⁷ In the trial, 25,584 patients, including 9603 with diabetes, were randomly assigned to treatment with ramipril, telmisartan, or both and observed for a mean follow-up period of 4.8 years. The primary endpoint, a composite of cardiovascular death, nonfatal MI, nonfatal stroke, and HF hospitalization, occurred in 20.2% of patients with diabetes and 14.2% of patients without diabetes. The patients with diabetes had a statistically significant 48% increased

risk for the primary endpoint, as well as statistically significantly increased risks of the component endpoint of cardiovascular death, MI, stroke, and congestive HF hospitalization. The relationship between blood pressure achieved and overall cardiovascular risk showed similar patterns in participants with and without diabetes, although diabetes shifted the relationship of cardiovascular events upward at any level of blood pressure achieved. In patients with and without diabetes, a progressively larger reduction in systolic pressure accompanied a reduction in risk of the primary outcome, but only if baseline pressure ranged from 143 to 155 mm Hg (except from stroke). In terms of fatal and nonfatal outcomes except for stroke events, reducing systolic pressure to less than 130 mm Hg in patients with diabetes had no further benefit. The incidence of stroke events was reduced down to on-treatment blood pressure levels of 115 mm Hg, with no evidence of an upward “J curve” inflection. A J curve relationship was observed with other endpoints. For the primary outcome, the nadir of the J curve was 129 mm Hg systolic blood pressure in both patients with and without diabetes. These observations parallel those from the ACCORD trial, and the most recent ADA guidelines for the management of patients with diabetes now incorporate these data, and endorse a blood pressure target of less than 140/80 mm Hg for all patients with diabetes and hypertension, with a more intensive blood pressure target of less than 130/80 mm Hg for those patients who can achieve it without “undue treatment burden.”¹⁶ (See also the Guideline section following [Chapter 44](#).)

Antihypertensive Therapy Summary

In summary, five classes of antihypertensive medications reduce CVD risk in patients with diabetes: ACE inhibitors, calcium channel blockers, beta blockers, thiazide diuretics, and ARBs. In addition, evidence supports a blood pressure target of less than 140/80 mm Hg for all patients with diabetes and hypertension, with a more intensive systolic pressure target of less than 130 mm Hg for those patients who can achieve that target without excessive adverse effects.

Antiplatelet Therapy

As discussed earlier, patients with diabetes have aberrations of platelet structure, function, and activity, yielding in aggregate a prothrombotic milieu. In addition, absolute or relative aspirin resistance may occur in up to 40% of patients with diabetes, with increasing prevalence associated with poor metabolic control. On the basis of these observations, much interest and investigation have focused on optimizing antiplatelet therapy for this high-risk cohort of patients.

Daily Aspirin

At present, the ADA and AHA recommend daily aspirin (75 to 162 mg/day) for all patients with diabetes who have established CVD, or for primary prevention in patients with diabetes older than 50 years of age for men or 60 years of age for women, with additional CVD risk factors (or younger in the presence of prevalent CVD risk).^{16,20} A substantial evidence base in the setting of secondary CVD risk modification supports these recommendations, but a recent meta-analysis of primary prevention with aspirin in patients with diabetes has not shown statistically significant benefit ([Fig. 61-7](#)).²⁰

Two randomized clinical trials currently are under way to explore further the role of aspirin in the setting of primary CVD risk prevention in type 2 diabetes. A Study of Cardiovascular Events In Diabetes (ASCEND) plans to enroll 10,000 patients with type 1 or type 2 diabetes without CVD, randomly assigned to treatment with 100 mg acetylsalicylic acid (ASA) daily or placebo, with a primary endpoint of major adverse cardiovascular events (<http://www.ctsu.ox.ac.uk/ascend/>). The Aspirin and Simvastatin Combination for Cardiovascular Events Prevention Trial in Diabetes (ACCEPT-D) plans to enroll 4700 patients with type 1 or type 2 diabetes to receive 100 mg ASA plus simvastatin, versus simvastatin alone, in a Prospective, Open-Label, Blinded Endpoint Evaluation (PROBE) design trial to assess the cardiovascular efficacy of ASA in primary prevention for patients with diabetes treated with statins.⁴⁸

In summary, until further evidence becomes available, daily aspirin (75 to 162 mg) is recommended for all patients with diabetes who

have CVD, or with increased CVD risk assessed by age older than 50 years for men and 60 years for women with additional CVD risk factors.^{16,20}

Thienopyridines

Accumulated data suggest that patients with type 2 diabetes require more aggressive antiplatelet treatment to alter CVD risk. Thienopyridines and nonthienopyridine antagonists of the platelet receptor P2Y₁₂ inhibit adenosine diphosphate (ADP)-induced activation of glycoprotein (GP) IIb/IIIa, a mediator of platelet aggregation, yielding more potent antiplatelet effects than those achieved with aspirin alone. Observations from trials of the thienopyridines clopidogrel and prasugrel, and the nonthienopyridine antagonist of the P2Y₁₂ receptor ticagrelor, support their efficacy in patients with diabetes in the chronic ambulatory setting—and as reviewed later in this chapter, in the setting of ACS.^{15,49} The CAPRIE (Clopidogrel versus Aspirin in Patients at Risk of Ischaemic Events) trial, which compared outcomes in patients with previous non-ST-segment elevation MI (NSTEMI), ischemic stroke, or established peripheral artery disease randomized to treatment with aspirin versus clopidogrel, enrolled 3866 patients with diabetes. In the subset of patients with diabetes, the 12.5% reduction in major adverse CVD events with clopidogrel versus aspirin paralleled the effect observed in the overall study cohort. In view of the incremental expense of clopidogrel and its associated increment in bleeding risk, however, this strategy is not routinely recommended over the use of aspirin alone for most patients, but clopidogrel remains an option for patients with aspirin indication but intolerance or allergy to aspirin.

Diabetes is associated with an increased prevalence of resistance to clopidogrel, a prodrug requiring metabolic conversion that tends to be impaired in diabetes, resulting in decreased circulating active metabolite.⁴⁹ These observations have led some investigators to explore the effects of increased dosing of clopidogrel in patients with diabetes, with preliminary data suggesting increased antiplatelet effects with such a strategy. The net clinical safety and efficacy of increased dosing of clopidogrel for chronic secondary prevention treatment, however, requires further evaluation before application in clinical practice.

Glucose Management

Numerous drug classes are approved for clinical use for the treatment of hyperglycemia associated with diabetes (Table 61-3). These drugs work by stimulating endogenous insulin release, impairing hepatic glucose production, improving the body's response to insulin, delaying intestinal carbohydrate absorption, providing exogenous insulin, or increasing glucose urinary losses.

FIGURE 61-7 Meta-analysis of trials examining the effects of aspirin on risk of cardiovascular disease events in patients with diabetes. **A**, Effect of aspirin on coronary heart disease events. Tests for heterogeneity: $\chi^2 = 8.71$, $P = 0.367$, $I^2 = 8.2\%$. **B**, Effect of aspirin on risk of stroke in patients with diabetes. Cardiovascular Effects of Selected Drugs for Diabetes

To date, the approval of drugs for diabetes depended almost exclusively on proof of glucose lowering without the requirement of demonstration of efficacy on clinical outcomes. The regulatory landscape for diabetes drugs has recently undergone major changes, such that all future diabetes drugs (and probably those currently on the market) must demonstrate designated margins of CVD safety to achieve or to maintain regulatory approval, leading to a rapid proliferation of clinical trials under way or in planning to assess CVD outcomes with these therapies⁵⁰ (Table 61-4). In this context, the available data on the net CVD safety and efficacy of such medications are limited, and current management strategies and guidelines remain grounded on the proven microvascular disease benefits demonstrated with glucose control.^{16,22}

TABLE 61-3 Glucose-Lowering Medications for Type 2 Diabetes Mellitus

CLASS	COMPOUND(S)	CELLULAR MECHANISM	PRIMARY PHYSIOLOGIC ACTION(S)	ADVANTAGES	DISADVANTAGES	COST
Biguanides	Metformin	Activates AMP-kinase	↓ Hepatic glucose production	Extensive experience No weight gain No hypoglycemia Likely ↓ CVD events (UKPDS)	Gastrointestinal side effects (diarrhea, abdominal cramping) Lactic acidosis risk (rare) Vitamin B ₁₂ deficiency Multiple contraindications: CKD, acidosis, hypoxia, dehydration, other	Low
Sulfonylureas	2nd-generation Glyburide/ glibenclamide Glipizide Gliclazide* Glimepiride	Closes K _{ATP} channels on beta cell plasma membranes	↑ Insulin secretion	Extensive experience ↓ Microvascular risk (UKPDS)	Hypoglycemia Weight gain ? Blunts myocardial ischemic preconditioning Low durability	Low
Meglitinides (glinides)	Repaglinide Nateglinide	Closes K _{ATP} channels on beta cell plasma membranes	↑ Insulin secretion	↓ Postprandial glucose excursions Dosing flexibility	Hypoglycemia Weight gain ? Blunts myocardial ischemic preconditioning Frequent dosing schedule	High
Thiazolidinediones	Pioglitazone Rosiglitazone†	Activates the nuclear transcription factor PPAR-γ	↑ Insulin sensitivity	No hypoglycemia Durability ↑ HDL-C ↓ Triglycerides (pioglitazone) ? ↓ CVD events (PROactive, pioglitazone)	Weight gain Edema/heart failure Bone fractures ↑ LDL-C (rosiglitazone) ? ↑ MI (meta-analyses, rosiglitazone) ? ↑ Bladder cancer (pioglitazone)	Moderate
α-Glucosidase inhibitors†	Acarbose Miglitol Voglibose*§	Inhibits intestinal α-glucosidase	Slows intestinal carbohydrate digestion/absorption	No hypoglycemia ↓ Postprandial glucose excursions ? ↓ CVD events (STOP-NIDDM) Nonsystemic	Generally modest HbA1c efficacy Gastrointestinal side effects (flatulence, diarrhea) Frequent dosing schedule	Moderate
DPP-4 inhibitors	Sitagliptin Vildagliptin* Saxagliptin Linagliptin Alogliptin	Inhibits DPP-4 activity, increasing postprandial active incretin (GLP-1, GIP) concentrations	↑ Insulin secretion (glucose-dependent) ↓ Glucagon secretion (glucose-dependent)	No hypoglycemia Well tolerated	Generally modest HbA _{1c} efficacy Urticaria/angioedema ? Pancreatitis Possible ↑ heart failure	High
Bile acid sequestrants†	Colesevelam	Binds bile acids in intestinal tract, increasing hepatic bile acid production; ? activation of farnesoid receptor (FXR) in liver	Unknown ? ↓ Hepatic glucose production ? ↑ Incretin levels	No hypoglycemia ↓ LDL-C	Generally modest HbA1c efficacy Constipation ↑ Triglycerides May ↓ absorption of other medications	High
Dopamine-2 agonists†	Bromocriptine (quick-release)§	Activates dopaminergic receptors	Modulates hypothalamic regulation of metabolism ↑ Insulin sensitivity	No hypoglycemia ? ↓ CVD events (Cycloset Safety Trial)	Generally modest HbA1c efficacy Dizziness/syncope Nausea Fatigue Rhinitis	High

METFORMIN. Metformin, in the biguanide class, lowers blood glucose primarily by decreasing hepatic glucose output and with some improvement in insulin sensitivity.⁵¹ In addition, metformin use is associated with weight reduction, favorable effects on lipid parameters, improved coagulation profiles, and low risk for hypoglycemia. In the United Kingdom Prospective Diabetes Study (UKPDS) of various glucose-lowering strategies in a population of patients with newly diagnosed type 2 diabetes, patients who were overweight at study entry were eligible for randomization to metformin therapy in addition to sulfonylureas, insulin, and usual care. Those treated with metformin had statistically superior outcomes for all diabetes endpoints, MI, and all-cause mortality compared with either of the other two drug treatment strategies or with usual care, observed for up to 10 years of posttrial follow-up.⁴

Concerns about metformin's potential to cause lactic acidosis delayed the regulatory approval of metformin in the United States and hindered its clinical uptake, stemming from observations with the earlier use of another biguanide, phenformin, which clearly caused lactic acidemia and was removed from the market on that basis. In response to this concern, metformin has been contraindicated for

use in the setting of impaired renal function; for 48 to 72 hours after the administration of iodinated contrast material; and in symptomatic HF. Of note, however, in the context of widespread global use of metformin for more than five decades and a substantial aggregated database of comparative clinical trials, a convincing signal for increased lactic acidemia with metformin treatment has not been identified.⁵² Although the renal impairment and contrast agent exposure contraindications remain on the U.S. product label, their relevance remains uncertain, and endocrine societies around the world have developed their guidance advisories in that regard, acknowledging that metformin use probably is safe in patients with estimated glomerular filtration rate (eGFR) down to 30 mL/min in most cases.^{22,53} The contraindication to use in HF was removed from all U.S. metformin product labels in 2006, on the basis of demonstrated clinical safety and observational associations of improved cardiovascular outcomes in the HF cohort among metformin-treated patients.⁵¹

On the basis of safety, tolerability, low hypoglycemia risk, cardiovascular clinical outcomes data, and relatively low cost of the generic formulation, metformin should be the first-line drug for type 2 diabetes in the absence of contraindications or intolerance.^{16,22,51} Metformin

NCT = National Clinical Trial [registration number]; Pio = pioglitazone; SU = sulfonylurea.

is the only oral therapy drug routinely recommended to be continued after initiation of insulin therapy.

SULFONYLUREAS. Sulfonylureas, in clinical use since 1950, are the oldest oral glucose-lowering drugs. They lower glucose by augmenting insulin release through inhibition of adenosine triphosphate (ATP)-dependent potassium (K_{ATP}) channels in pancreatic beta cells. Although these drugs typically are well tolerated and are relatively potent, their use results in the highest rate of hypoglycemia of any available oral drug and is associated with weight gain. Although tolbutamide, a first-generation sulfonylurea, increased cardiovascular and all-cause mortality in an early randomized trial, no such adverse cardiovascular safety signals have emerged from subsequent randomized trials with assignment to second-generation and third-generation sulfonylureas.⁵¹ On the basis of the extensive clinical experience, the availability of low-cost generics, and the efficacy of glucose control demonstrated in several clinical trials, sulfonylureas have been endorsed among the second-line drugs (after metformin) for the treatment of type 2 diabetes.²²

Concerns persist, however, about the use of sulfonylureas in CVD cohorts, driven by the weight gain associated with the drugs, the increased risk for hypoglycemia and commensurate stimulation of the adrenergic stress-response system with potential adverse CVD effects, and the potential of these drugs to inhibit so-called ischemic preconditioning through blockade of myocardial K_{ATP} channels.⁵¹ In animal models of MI, activation of myocardial K_{ATP} channels reduces infarct size—an effect termed *ischemic preconditioning* that is blocked by sulfonylureas. The relevance of these observations in humans remains poorly understood, but this blocking effect is one potential explanation for the increased MI case-fatality rate observed in the more intensively treated patients in the ACCORD trial—a conjecture that remains unproved owing to limited ability to analyze outcomes according to drug allocation in that trial.⁵ Observations from the UKPDS trial counter the likelihood of such an effect, because an intensive glucose control policy with two different sulfonylureas—chlorpropamide and glyburide—yielded MI and cardiovascular death outcomes similar to those with insulin.⁴

On the basis of these concerns, sulfonylureas that are relatively specific for pancreatic K_{ATP} channels have been developed—such as

glimepiride—although no cardiovascular clinical outcomes trials have yet evaluated the cardiovascular safety and efficacy of these newer members of the class. More recent observational data deriving from a Danish national registry, however, support ongoing concerns with regard to the all-cause and cardiovascular mortality effects of sulfonylureas, with statistically significant increased odds for multivariable and propensity adjustment associated with all sulfonylureas analyzed compared with metformin, including the pancreatic-specific glimepiride, with the exception of gliclazide with no associated mortality signal—a drug not approved for use in the United States.⁵⁴

DIPEPTIDYL PEPTIDASE 4 INHIBITORS. Dipeptidyl peptidase 4 (DPP-4) inhibitors selectively inhibit the action of DPP-4, an enzyme that degrades the endogenous incretin glucagon-like protein (GLP)-1, which inhibits glucagon release. Inhibiting DPP-4 raises GLP1-levels, decreases glucagon release, and increases insulin secretion, thereby decreasing glucose levels. Four DPP-4 inhibitors—saxagliptin, alogliptin, sitagliptin, and linagliptin—have been approved for clinical use in the United States, with a fifth drug (vildagliptin) approved elsewhere. Each of these is provided as a once-daily dosed tablet, with modest glucose-lowering potency and with the clinical benefits of neutral effects on weight and low risk for hypoglycemia. In meta-analyses of phase II data across this class of drugs, treatment with DPP-4 inhibitors statistically reduced the risk of major cardiovascular events (odds ratio, 0.71 [95% CI, 0.59 to 0.86]),⁵⁵ a combined dataset comprising a total of only 495 major adverse cardiovascular events (MACEs) for analysis observed during a mean follow-up period of only 44 weeks, challenging generalizability to longer treatment periods. Randomized cardiovascular outcomes trials of two of these drugs have been completed, with three other trials ongoing (see Table 61-4).

In the Saxagliptin Assessment of Vascular Outcomes Recorded in Patients with Diabetes Mellitus (SAVOR)—Thrombolysis in Myocardial Infarction (TIMI) 53 trial, 16,492 patients with type 2 diabetes with or at increased risk for atherosclerotic cardiovascular disease were randomly assigned to blinded treatment with saxagliptin 5 mg daily (or 2.5 mg daily in patients with an estimated glomerular filtration rate [eGFR] of ≤ 50 mL/min) versus placebo, added to background diabetes treatment, with use of open-label glucose-lowering therapies

(excluding DPP-4 antagonists) to achieve standard-of-care glycemic targets in patients in both study arms.⁵⁶ Over a median follow-up period of 2.1 years, saxagliptin neither increased nor reduced risk for the primary endpoint of MACEs—a composite of cardiovascular death, MI, and ischemic stroke (HR, 1.00 [95% CI, 0.89 to 1.12]; $P < 0.001$ for noninferiority and $P = 0.99$ for superiority). An unexpected observation in this trial was an increase in risk for hospitalization for HF associated with saxagliptin (289 versus 228 events—3.5% versus 2.8%; HR, 1.27 [95% CI, 1.07 to 1.51]), an observation that remains poorly understood and requires further exploration and assessment in the other outcomes trials evaluating the DPP-4 antagonists.

In the Examination of Cardiovascular Outcomes with Alogliptin versus Standard of Care (EXAMINE) trial, 5380 patients with type 2 diabetes and a recent ACS event were randomly assigned to blinded treatment with alogliptin or to receive placebo.⁵⁷ Because alogliptin is cleared renally, doses were adjusted based on eGFR, with use of 25 mg in patients with an eGFR of 60 mL/min/1.73 m² of body surface area or greater; 12.5 mg with eGFR 30 to below 60 mL/min/1.73 m²; and 6.25 mg for eGFR below 30 mL/min/1.73 m². As with SAVOR-TIMI 53, open label glucose-lowering treatment (excluding DPP-4 antagonists) was allowed for both groups. With the same primary endpoint as in the SAVOR-TIMI 53 trial, alogliptin did not increase the incidence of the primary endpoint (hazard ratio, 0.96; upper 97.5% confidence limit = 1.16; $P < 0.001$ for noninferiority). No cases of HF were reported in the primary trial publication.

THIAZOLIDINEDIONES. Thiazolidinediones (e.g., rosiglitazone, pioglitazone) decrease glucose levels in type 2 diabetes by increasing the insulin sensitivity of target tissues and induce a wide variety of nonglycemic effects mediated through activation of the nuclear receptor PPAR- γ , including some favorable effects on intermediate markers of CVD and CVD risk, leading to much interest in their effects on CVD morbidity and mortality.⁵⁸ In the Prospective Pioglitazone Clinical Trial in Macrovascular Events (the PROactive study), the first randomized trial designed to assess the effect of any glucose-lowering medication on cardiovascular clinical outcomes, treatment with pioglitazone yielded a significant 16% relative risk reduction for the prioritized secondary composite endpoint of all-cause mortality, nonfatal MI, and stroke compared with placebo in patients with type 2 diabetes and prevalent CVD at study entry, treated during a 34.5-month follow-up period, although the effect on the primary endpoint did not achieve statistical significance.⁵⁹ By contrast, rosiglitazone may increase CVD risk—and, specifically, MI risk.⁵⁸ Although the data are not definitive, the signal for increased MI risk with rosiglitazone has led to severe product label restrictions for use in the United States, and to withdrawal of the drug from the market elsewhere.

Both rosiglitazone and pioglitazone increase the risk for peripheral edema, with a small but consistent increase in risk for new or worsening HF.⁵⁸ On that basis, the product labels for both agents warn against their use in patients with HF, with a contraindication to initiation in patients with New York Heart Association (NYHA) class III or IV HF and a caution against their use in any patient with HF. Although the mechanism of the observed increase in edema and HF remains unclear, it appears to result primarily from increased renal sodium reclamation and plasma volume expansion, with no evidence to date of pernicious cardiac effects of these drugs.^{58,60}

INSULIN. Suggested CVD benefits with insulin derive from selected trials including both type 2 and type 1 diabetes, but these studies all had limited statistical power to assess such effects. Most recently, results emerged from the Outcome Reduction with an Initial Glargine Intervention (ORIGIN) trial. This study randomly assigned 12,537 patients with cardiovascular risk factors plus impaired fasting glucose, impaired glucose tolerance, or prevalent type 2 diabetes to treatment with insulin glargine or standard care management, with dual primary trial outcomes of (1) nonfatal MI, nonfatal stroke, or death from cardiovascular causes and (2) these events plus revascularization or hospitalization for HF.⁶¹ After a median follow-up period of 6.2 years, no differences were found between the insulin glargine and placebo groups in the rate of the first coprimary outcome (2.94

versus 2.85 events per 100 patient-years; $P = 0.63$) or the second coprimary outcome (5.52 versus 5.28/100 person-years; $P = 0.27$). Although ORIGIN did not demonstrate superiority of insulin glargine, the coprimary outcomes had point estimates of effect of 1.02 and 1.04, respectively, both with an upper confidence limit of 1.11—well within the current regulatory standard of upper confidence limit for cardiovascular effects of less than 1.3 to demonstrate cardiovascular safety of glucose-lowering drugs. As expected, insulin use was associated with more hypoglycemia and weight gain; of importance, no increased risk for cancer was observed with insulin glargine, refuting a substantial body of epidemiologic data suggesting such an increased risk.

DOPAMINE D₂ RECEPTOR AGONIST. Quick-release bromocriptine (bromocriptine-QR) is an agonist of the D₂ dopamine receptor, initially introduced for clinical use in treatment of hyperprolactinemia and also used to treat acromegaly, Parkinson's disease, and neuroleptic malignant syndrome. It has subsequently been developed and approved (in the United States only) for the treatment of hyperglycemia in type 2 diabetes. Although the mechanism of the glucose-lowering effect remains poorly understood, it appears to augment central nervous system (CNS) dopamine levels and to inhibit excessive sympathetic tone, resulting in reduced postprandial hepatic glucose output, with neutral effects on weight, lipids, and blood pressure and low rates of hypoglycemia. In a randomized 52-week cardiovascular safety trial enrolling 3095 patients with type 2 diabetes, randomly assigned in 2:1 ratio to receive bromocriptine-QR (quick release) or placebo, a significant reduction in a composite cardiovascular outcome of MI, stroke, coronary revascularization, and hospitalization for angina or congestive HF was achieved with bromocriptine-QR versus placebo (1.8% versus 3.2%, respectively; HR, 0.60 [95% CI, 0.35 to 0.96]), although only 69 cardiovascular events were available for analysis, yielding significant uncertainty with regard to the precision of the estimated efficacy.⁶² Owing largely to a relatively sparse dataset, however, the clinical use of bromocriptine-QR in the treatment of type 2 diabetes has been limited, and the most recent treatment algorithm from the ADA/European Association for the Study of Diabetes (EASD) does not endorse the drug.²²

OTHER GLUCOSE-LOWERING MEDICATIONS. Limited data are available with regard to CVD outcomes with other glucose-lowering medications, with numerous new classes of medications recently becoming available or in late stages of phase III investigation, summarized in Table 61-4.⁵¹ These newer agents share the advantage of a very low risk for hypoglycemia, and many are weight-neutral or cause weight loss. Colesevelam, a bile acid sequestrant initially approved for the treatment of hypercholesterolemia, has now received approval for use as a glucose-lowering drug to treat diabetes, and alpha-glucosidase inhibitors retard intestinal carbohydrate absorption. The effects of these drugs on cardiovascular outcomes remains unknown, and gastrointestinal intolerance has limited their clinical use.²² Injectable analogues of the incretin hormone GLP-1 augment glucose-appropriate insulin secretion.⁵¹ Meta-analysis of small studies with notably few cardiovascular events across this class of medications suggests that they may reduce CVD risk,^{63,64} although the definitive trials assessing such effects are ongoing. Antagonists of the renal sodium-glucose transporter-2 (SGLT-2) inhibit urinary glucose reclamation, leading to increased urinary glucose losses with resultant caloric losses of up to 400 kcal/day, yielding significant weight loss.⁶⁵ As osmotic diuretics, SGLT-2 antagonists also are associated with blood pressure reduction. Definitive cardiovascular outcomes trials are under way.

Cardiovascular Effects of More Intensive versus Less Intensive Glucose Control Strategies

The UKPDS trial⁴ randomly assigned 5102 patients with newly diagnosed type 2 diabetes to intensive glucose control with sulfonylurea or insulin or to management with diet alone; those overweight at study entry ($n = 795$) also could be randomly chosen for the intensive arm to receive metformin. In the insulin and sulfonylurea analyses, showing hemoglobin A1c (HbA1c) levels of 7.0% and 7.9%,

respectively, during an average follow-up period of 10 years, intensive control decreased risk for a composite endpoint of all diabetes-related complications (RRR, 12%; $P = 0.029$) and significantly improved microvascular disease risk (RRR, 25%; $P = 0.01$). Although a trend toward decreased risk of MI was observed with intensive control (14.8% versus 16.8%; $P = 0.052$), the number of strokes was increased, although the difference did not achieve statistical significance (5.6% versus 5.2%; $P = 0.52$). In overweight subjects, metformin yielded better glucose control (HbA1c 7.4% versus 8.0%) and significantly decreased risk for MI (RRR, 39%; $P = 0.01$) and all-cause mortality (RRR, 36%; $P = 0.011$). The publication of results derived from long-term post-trial follow-up of the UKPDS trial cohort has extended these observations to an average duration of 10 years after completion of the trial,⁴ during which glucose control converged rapidly after the study treatment discontinuation. These analyses reveal a significantly reduced risk for MI in those originally randomly assigned to intensive control, both in the insulin and sulfonylurea group (RRR, 15%; $P = 0.01$) and in the metformin group (RRR, 33%; $P = 0.005$). The continued divergence of the cardiovascular event curves throughout the entire post-trial follow-up after randomized study treatment was discontinued and despite rapid convergence of glucose control at study end suggests a legacy cardiovascular benefit of early assiduous glycemic control, a finding similarly observed in the long-term follow-up period of the Diabetes Control and Complications Trial (DCCT) in patients with type 1 diabetes.⁶⁶

More recently, the results from three trials assessing the CVD effects of more intensive versus standard glucose control among patients with type 2 diabetes at high cardiovascular risk have become available^{5,6,67,68} (Table 61-5). Comprising more than 23,000 patients treated on study protocol from 3 to 5 years, all three trials showed no significant CVD benefit of intensified glucose control.

The ACCORD trial compared intensive versus standard glucose control in 10,251 patients with type 2 diabetes who were at high CVD risk, achieving HbA1c contrast of 6.4% versus 7.5%.⁶⁸ This trial was stopped early at the recommendation of the data safety monitoring committee because of an excess of all-cause mortality (257 versus 203 events; $P = 0.04$) in the intensively treated group, with no significant difference observed in the primary composite CVD endpoint of

cardiovascular death, MI, and stroke (HR, 0.90 [95% CI, 0.78 to 1.04]). The initial trial observations persisted through up to 17 months of posttrial follow-up in this cohort,⁶⁸ during which the primary composite outcome risks remained similar between groups, and the risk of death from any cause was 19% higher in patients randomly assigned to the more intensive glucose control strategy in the trial ($P < 0.05$) and the HR for nonfatal MI was 0.83 ($P < 0.05$). The basis for the increased mortality remains unresolved; possible explanations currently under exploration include increased hypoglycemia precipitating cardiovascular death, pernicious effects of specific drugs or drug combinations, and a chance finding in the context of the other recently reported trials. More than 75% of the intensively treated patients were treated with insulin during the trial, and most patients received three or more oral agents simultaneously. The absence of randomization to specific therapies renders post hoc analysis of cause especially difficult.

The ADVANCE trial enrolled 11,140 patients with type 2 diabetes who had CVD, microvascular disease, or another vascular risk factor at study entry.⁶ The patients were randomly assigned to either intensive or standard glucose control with gliclazide plus other drugs in the intensive arm, compared with other drugs in the standard control group. Similar to the ACCORD trial, the ADVANCE trial failed to achieve statistically significant improvement in the composite CVD outcome of cardiovascular death, MI, and stroke with intensive control (achieved HbA1c of 6.4% versus 7.0%), despite the ascertainment of 1147 events (10.0% versus 10.6%; RRR, 6% [95% CI, -6% to 16%]).

In the Veterans Affairs Diabetes Trial (VADT), 1791 U.S. veterans with type 2 diabetes and inadequate glucose control were randomly assigned to either intensive or standard glucose control.⁶⁷ Despite a wide separation in glucose control values (HbA1c of 6.9% versus 8.4%) and ascertainment of 499 primary MACEs, this trial also found no significant improvement in cardiovascular outcomes with intensive control (29.5% versus 33.5%; $P = 0.14$).

From post hoc analyses of data for each of these recent trials and supported by the long-term observations reported from UKPDS in patients with newly diagnosed diabetes at study entry, the concept has emerged that more intensive glycemic control may both be safer and have more favorable cardiovascular effects when used in patients

TABLE 61-5 Baseline Characteristics and Main Results from Three Large Randomized Cardiovascular Trials in Patients with Type 2 Diabetes Mellitus

STUDY FEATURE/RESULT	ACCORD		ADVANCE		VADT	
No. of patients	10,251		11,140		1791

ACCORD = Action to Control Cardiovascular Risk in Diabetes trial⁵; ADVANCE = Action in Diabetes and Vascular disease: preterAx and diamicroN-MR Controlled Evaluation trial⁶; BMI = body mass index; CV = cardiovascular; VADT = Veterans Affairs Diabetes Trial.⁶⁷

Modified from Gore MO, Inzucchi SE, McGuire DK: Diabetes and cardiovascular disease. In Blumenthal RS, Foody JM, Wong ND, editors. *Prevention of Cardiovascular Disease: A Companion to Braunwald's Heart Disease*. 1st ed. Philadelphia, Saunders, 2011, p 345-70.

earlier in the course of diabetes, particularly among those without prevalent CVD. The corollary to this strategy is that more liberal glycemic targets may be acceptable for selected patients at increased risk, such as very elderly patients, those with a high burden of underlying comorbidity, and specifically those with prevalent CVD. Support for this strategy derives from an observational analysis of more than 25,000 patients enrolled in the Kaiser Permanente Northwest health care system that analyzed cardiovascular and all-cause mortality outcomes according to achieved HbA1c, demonstrating a U-shaped relationship with statistically incremental cardiovascular disease risk similarly observed at HbA1c values less than 6.9% and greater than 8.5%, raising the possibility of adverse CVD and mortality risk associated with more strict control than advocated by present guidelines and evidence.⁶⁹ Although these hypotheses require confirmation in additional clinical trials, the most recent ADA/EASD guidelines for chronic glucose management for patients with type 2 diabetes endorse such a strategy of targeting intensity of glucose control in the context of global CVD risk.^{16,22}

In summary, whereas these recent randomized trials did not demonstrate significant incremental cardiovascular benefits with more intensive glucose control, the analyses of the primary composite endpoints for each trial revealed point estimates of relative risk reductions ranging from 6% to 12%, each with upper 95% confidence limits of 1.04 to 1.06. Such results provide significant assurance of a margin of cardiovascular safety with more intensive glucose control, supported by recently published meta-analyses of the available data, demonstrating statistically significant reductions in MI (HR, 0.83 [95% CI, 0.75 to 0.93]), with no significant effects on stroke (HR, 0.93 [95% CI, 0.81 to 1.06]) or all-cause mortality (HR, 1.02 [95% CI, 0.87 to 1.19]).²¹ These observed upper confidence limits are well within the noninferiority margins recently adopted by U.S. and European regulatory agencies for diabetes drug registration⁵⁰ to exclude the upper noninferiority 95% confidence limit of 1.3 (or 97.5% certainty of no greater than 30% worse than comparator) for cardiovascular safety.

Comparative Effectiveness of Insulin Provision Versus Insulin Sensitization

In a trial comparing two strategies for glucose control (as opposed to different intensities), the Bypass Angioplasty Revascularization Investigation 2 Diabetes (BARI 2D) trial enrolled patients with type 2 diabetes and prevalent obstructive coronary disease, randomized to insulin provision therapy (IP) (insulin or sulfonylurea) versus insulin sensitization (IS) (metformin or thiazolidinedione).⁷⁰ In a sample of 2368 patients with the coprimary endpoints of all-cause mortality and the composite of cardiovascular death, MI, and stroke (MACEs), and with an average study treatment duration of 5.3 years, no statistical difference between the two glucose treatment strategies was found with either of the primary endpoints, in the context of a difference in achieved HbA1c of 0.5% favoring IS (7.0% versus 7.5%; $P < 0.001$). All-cause mortality occurred in 115 patients in the IP group versus 117 in the IS group (11.8% versus 12.1%; $P = 0.89$), and the primary MACE composite occurred in 218 versus 238 patients (22.3% versus 24.6%; $P = 0.13$). Peripheral edema was more common in the IS group (56.6% versus 51.9%; $P = 0.02$), and hypoglycemia was much more common in the IP group (53.3% versus 73.8%; $P < 0.001$). The nearly exclusive use of rosiglitazone as the thiazolidinedione treatment in this trial confounds its interpretation, given this agent's uncertain cardiovascular effects (as outlined earlier.) Also, there was a relatively high rate of crossover treatment between the randomized groups—especially in the IS group, requiring the addition of sulfonylurea or insulin to maintain targeted glucose control.

Summary of Glucose Management

While intensive glucose control favorably affects microvascular disease risk, its importance in CVD risk modification remains uncertain. Reflecting the accumulated data, the most recent guidelines from the ADA and EASD endorse a more individualized approach than previously recommended, with more liberal HbA1c targets for patients with shorter expected lifespans and with significant comorbidity including prevalent cardiovascular disease (Fig. 61-8),

suggesting a HbA1c target of 8% (or higher).^{16,22} In addition, in the context of the paucity of clinical outcomes data for most therapies used for type 2 diabetes, the ordered addition of subsequent glucose-lowering medications after metformin is left to the discretion of the provider, taking individual patient and drug characteristics into such treatment determinations.

Acute Coronary Syndromes

In view of the high risk associated with diabetes in the setting of ACS, much investigation has focused on this population. In general, as endorsed by the most recent ACS guidelines,^{41,71} the treatment of patients with diabetes should mimic that of the overall population (see Chapters 51 to 53). Some specific therapies also are recommended for patients with diabetes.

Insulin and Glucose Control

The myocardium preferentially metabolizes free fatty acids under physiologic conditions, but it can also metabolize a variety of substrates during periods of stress (such as ischemia), principally glucose. Countering the metabolic switch to glucose metabolism during ischemia, the myocardium develops a relative insulin resistance, underpinning extensive research into metabolic modulation of the ischemic myocardium, with insulin as the primary focus of investigation. But it is critical to differentiate study results in ACS populations deriving from protocols designed to deliver high-dose insulin supported by exogenous glucose administration (i.e., glucose-insulin-potassium [GIK] therapy), comprising virtually the entirety of data in this area, contrasted with the evaluation of insulin administration to achieve targeted glucose control, for which no large-scale cardiovascular clinical outcomes trials exist to date (Table 61-6).

Glucose-Insulin-Potassium Therapy

The use of insulin for ACS was first described in 1963 by Sodi-Pallares, with the intention of facilitating potassium flux in the ischemic myocardium, the so-called “polarizing therapy.” After decades of investigation, this combination of glucose, insulin, and potassium has become known as GIK therapy, and the focus of attention has shifted from the polarizing effects to the direct effects of insulin, including promotion of myocardial glucose oxidation, reduction of circulating nonesterified free fatty acids that may contribute to myocardial injury through an increased oxygen demand associated with free fatty acid metabolism and resultant accumulation of toxic free fatty acid metabolites, improved coagulation parameters, and anti-inflammatory effects⁷² (Fig. 61-9). Despite these proposed mechanistic benefits of insulin and the suggestion of clinical benefit derived from numerous small trials of GIK therapy, the strategy proved futile in a trial comprising 20,201 patients with ST-elevation MI (STEMI), randomized to GIK therapy versus usual care and accumulating 1980 mortality events—demonstrating no benefit of GIK therapy compared with usual care (10.0% versus 9.7%; HR, 1.03 [95% CI, 0.95 to 1.13]).⁷³ The GIK protocol specifies high-dose insulin supported by glucose administration to maintain modest levels of hyperglycemia (to avoid hypoglycemia), notably contrasted with targeting normal glucose levels with insulin (see Table 61-6).

Targeted Glucose Control

To date, no large-scale clinical trial has assessed the cardiovascular effect of intensive glucose control in the setting of ACS events. The Diabetes Mellitus Insulin-Glucose Infusion in Acute Myocardial Infarction (DIGAMI) trial enrolled 620 patients with hyperglycemia at presentation with MI, randomly assigned to insulin infusion acutely, followed by multidose subcutaneous insulin injection, or usual care, with significant mortality reduction demonstrated in the insulin-treated group during long-term follow-up.⁷⁴ DIGAMI used an acute infusion of high-dose insulin (5 units/hr), coupled with intravenous glucose administration with protocol-targeted hyperglycemia ranging from 126 to 198 mg/dL, an insulin dosing protocol that has been used in each subsequent GIK trial (see Table 61-6). Often

APPROACH TO MANAGEMENT OF HYPERGLYCEMIA

MORE STRINGENT

LESS STRINGENT

FIGURE 61-8 Depiction of the elements of decision making used to determine appropriate efforts to achieve glycemic targets. Greater concerns about a particular domain are represented by increasing height of the ramp. Thus characteristics/predicaments toward the left justify more stringent efforts to lower HbA1c, whereas those toward the right are compatible with less stringent efforts. When possible, such decisions should be made in conjunction with the patient, reflecting his or her preferences, needs, and values. This “scale” is not designed to be applied rigidly but rather is meant to be used as a broad construct to help guide clinical decisions. (From Inzucchi SE, Bergenstal RM, Buse JB, et al: *Management of hyperglycemia in type 2 diabetes: A patient-centered approach: Position statement of the American Diabetes Association (ADA) and the European Association for the Study of Diabetes (EASD)*. *Diabetes Care* 35:1364, 2012.)

misinterpreted as a trial of intensive glucose control, this study has provided the basis of guideline recommendations for intensive glucose control in the management of ACS events since 2004, advocating normalization or near-normalization of blood glucose concentration.^{41,75} Nevertheless, in the wake of numerous randomized trials in noncardiac intensive care unit (ICU) populations demonstrating no benefit at best, and increased mortality associated with insulin infusions to normalize blood glucose concentration at worst⁷⁶⁻⁸⁰ (Table 61-7), professional guidelines have evolved substantially toward much more conservative targets in the care of patients with ACS events, recommending insulin infusion to achieve targets of less than 180 mg/dL.^{71,81}

The risk of hypoglycemia associated with intensive glucose control in acutely ill patients remains an important concern, with an incidence of severe hypoglycemia as high as 19% observed in the reported randomized trials. This concern may be especially important in the treatment of ACS, in which the counterhormone response associated with hypoglycemia may prove to be particularly deleterious to ischemic and infarcting myocardium. Data from observational studies have shown increased risk associated with hypoglycemia among ACS cohorts, but whether hypoglycemia simply marks disease severity or contributes to adverse outcomes remains unclear.⁸¹ In the Normoglycemia in Intensive Care Evaluation–Survival Using Glucose Algorithm Regulation (NICE-SUGAR) trial,⁸⁰ the incidence of

hypoglycemia associated with the insulin infusion was the lowest (6.8%) among of all reported trials, yet this is the only trial to demonstrate statistically significant increased mortality with intensive glycemic control in the ICU setting, raising the possibility that alternative mechanisms may mediate the adverse effects of the insulin infusion. The importance of this observation is that the ability to avoid excess hypoglycemia should no longer justify the continued use of insulin infusions targeting tight glycemic control.

Few of the reported trials assessing targeted glucose control in ICU settings included patients with ACS events, so the generalizability of the observations remains uncertain. In this context and with the paucity of data in the ACS setting, a more conservative approach to glucose management should be used for patients with ACS events

than has previously been recommended. The most recently recommended glucose targets of below 180 mg/dL are most reasonable, based on existing data.^{71,81}

Antiplatelet Drugs

Aspirin therapy is effective in an ACS setting, with or without diabetes. Because of the aberrations of platelet function associated with diabetes, however, significant interest and investigations have centered on the potential for more intensive antiplatelet therapies to provide particular benefit to patients with diabetes who are experiencing ACS events. Support for this concept derives from clinical trial data of thienopyridine medications and GP IIb/IIIa antagonists.

Thienopyridines and Nonthienopyridine Antagonists of the Platelet P2Y₁₂ Receptor

The incremental efficacy of adding thienopyridine and nonthienopyridine antagonists of the platelet receptor P2Y₁₂ (clopidogrel, prasugrel, and ticagrelor) to aspirin therapy in the treatment of ACS (see Chapters 52 and 53) has been demonstrated in randomized clinical trials that included substantial numbers of patients with diabetes.^{15,82-84} In the Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial,⁸² which included 2840 patients with diabetes, the estimate of treatment benefit of clopidogrel in this subpopulation of 15% RRR was numerically similar to the overall trial results (14.2% versus 16.7%; *P* > 0.05). Prasugrel (a third-generation thienopyridine) added to aspirin therapy, compared with clopidogrel plus aspirin, demonstrated significantly reduced CVD risk in the diabetes subset of the Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel-Thrombolysis in Myocardial Infarction 38 (TRITON-TIMI 38) trial, including patients with ACS undergoing a primary invasive management strategy (12.2% versus 17.0%; *P* < 0.001).⁹ Of note, the incremental reduction in CVD risk with prasugrel within the diabetes subset did not entail a significant increase in major bleeding complications (2.6% versus 2.5%). The subsequent Targeted Platelet Inhibition to Clarify the Optimal Strategy to Medically Manage Acute Coronary Syndromes (TRILOGY ACS) trial, however,

which enrolled patients with MI treated medically without revascularization, randomly assigned to treatment with clopidogrel or prasugrel,⁸⁵ found no significant differences between the groups in the primary composite outcome of cardiovascular death, MI, and stroke in the overall trial population, or in the diabetes subset, in which the interaction of treatment efficacy of prasugrel by diabetes status observed in the TRITON trial was not evident. Finally, in the PLATElet inhibition and patient Outcomes (PLATO) trial, which enrolled 18,624 patients with an ACS, with or without ST-segment elevation, randomly assigned to receive ticagrelor or clopidogrel, ticagrelor (a nonthienopyridine P2Y₁₂ antagonist) was associated with a significant reduction in the primary composite outcome of death from vascular causes, MI, and stroke (9.8% versus 11.7%; $P < 0.001$).⁸⁴ Similar findings pertained in the subset of 4662 patients with diabetes at study entry.⁸⁶ In aggregate, these observations support the incremental benefits of more potent antiplatelet treatment added to aspirin therapy in diabetes patients with ACS events, and they should be part of routine clinical management.

Glycoprotein IIb/IIIa Blockers

The GP IIb/IIIa inhibitors potently inhibit platelet aggregation (see Chapter 82). In current clinical practice, eptifibatide and tirofiban are approved for use in the setting of ACS; abciximab is approved for percutaneous coronary intervention (PCI) but not specifically for ACS. On the basis of results from a meta-analysis of the GP IIb/IIIa antagonists trials for the treatment of ACS events, demonstrating a significant mortality benefit with GP IIb/IIIa blockers in the subset with diabetes but not in the nondiabetic subjects, the use of GP IIb/IIIa antagonists for patients with diabetes suffering an ACS event is a level I (A) recommendation in the ACC/AHA guidelines.⁴¹

Renin-Angiotensin-Aldosterone System Antagonists

The ACE inhibitors have several favorable effects in the setting of ACS events that may be especially beneficial in the setting of diabetes, including improvements in ventricular structure and function, endothelial function, fibrinolytic system, and metabolic and neurohormonal effects. On the basis of observational data and subanalyses of diabetic patients in randomized trials, beneficial effects on HF incidence and mortality appear greater in the setting of diabetes. Thus, the routine use of ACE inhibitors for patients with diabetes is a level I (A) recommendation across the spectrum of ACS events.^{41,71}

Although ARBs have similar effects on intermediate markers of myocardial structure and function to those of ACE inhibitors, the evidence base with regard to their overall effects on clinical outcomes remains less robust, especially for the subset of patients with diabetes. For example, in the Optimal Trial in Myocardial Infarction with Angiotensin II Antagonist Losartan (OPTIMAAL), a randomized trial comprising patients with MI events complicated by HF, losartan versus captopril associated with a trend toward increased mortality (RR, 1.13 [95% CI, 0.99 to 1.28]; $P = 0.07$), although the observed differences were not statistically significant.⁸⁷ In contrast, in the Valsartan in Acute Myocardial Infarction Trial (VALIANT), which enrolled patients within 10 days of an acute MI complicated by HF, including 3400 patients with diabetes, showed no significant difference in mortality between patients randomly assigned to treatment with captopril and those treated with valsartan, with effects in the diabetes subset mirroring those observed in the overall study cohort.⁸⁸

In addition to its effects on sodium retention and potassium excretion, aldosterone also may directly stimulate the production of inflammatory mediators, cause myocardial fibrosis, and promote endothelial dysfunction and vascular stiffening, prompting investigation of the role of aldosterone blockade in the setting of ACS. The Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS), compared the mineralocorticoid-selective aldosterone antagonist eplerenone to placebo, added to optimal therapy, in a population of 6632 patients with MI and decreased ejection fraction who had either clinical HF or, in the absence of manifest HF, diabetes.⁸⁹ In the overall study cohort, treatment with eplerenone compared with placebo reduced the risk of cardiovascular death by 17% (RR, 0.83 [95% CI, 0.72 to 0.94]), with numerically similar

observations in the subset of 2232 patients with diabetes. On the basis of this trial, the use of an aldosterone antagonist for patients with diabetes and reduced ejection fraction after MI is recommended across the spectrum of ACS events,^{41,71} with the important caveat that such therapy should not be used in patients with impaired renal function (creatinine > 2.0 mg/dL) or hyperkalemia (potassium concentration > 5.0 mEq/liter). In addition, patients with diabetes should have serial monitoring of potassium concentration, given the high prevalence of type 4 renal tubular acidosis in the diabetes population.

Beta-Adrenergic Blocking Agents

Despite evidence of their incremental effectiveness in the treatment of patients with diabetes after ACS events, beta blockers continue to be underprescribed in this group. Biologic effects that support the incremental efficacy of beta blockers in the setting of diabetes include the restoration of sympathovagal balance in diabetic patients with autonomic neuropathy and decreasing fatty acid metabolism within the myocardium, reducing myocardial oxygen demand. Therefore they should be prescribed for all patients after ACS events, independent of diabetes status, unless other contraindications exist.^{41,71}

Primary Invasive Strategy for Non-ST-Segment Elevation Acute Coronary Syndromes

In randomized trials comparing primary invasive versus noninvasive strategies for the treatment of ACS events, the subsets of patients with diabetes have derived benefits similar to or greater than those of nondiabetic patients associated with a primary invasive management strategy, although mortality and reinfarction rates were still higher in the groups with diabetes in both treatment arms⁴¹ (see Chapter 53). Despite these benefits, a primary invasive strategy for patients with diabetes continues to be underused in patients with ACS events.⁸

Primary Reperfusion Therapy for ST-Segment Elevation Myocardial Infarction

Early in the development of thrombolytic therapy, concern arose about the potential for such intervention to cause retinal hemorrhage in patients with diabetes, in view of the prevalence of background diabetic retinopathy. Analyses of diabetic subsets in randomized trials of thrombolytics have not borne out such concerns. Indeed, the group with diabetes has derived much greater absolute benefit from thrombolytic therapy than nondiabetic patients.⁹⁰ Similarly, analyses from trials of primary PCI suggest greater benefit among patients with diabetes, with primary angioplasty proving superior to thrombolysis in these patients.⁹¹ Therefore patients with diabetes should undergo reperfusion therapy in the absence of other contraindications, preferentially with a strategy of primary PCI when it is available (see Chapter 52).

Coronary Revascularization Considerations Percutaneous Coronary Intervention

The optimal strategy of coronary revascularization for patients with diabetes remains controversial (see Chapter 54). Although initial success rates in diabetic and nondiabetic patients are similar, diabetic patients exhibit higher restenosis rates after PCI and worse long-term outcomes. The mechanism underlying the increased restenosis rate in diabetes after coronary intervention is unclear. A variety of metabolic and anatomic abnormalities associated with diabetes and a greater degree of plaque burden may contribute to restenosis in diabetic patients. Although drug-eluting stents have reduced the need for target lesion revascularization in these patients, supporting their preferential use, these patients still experience more restenosis (see Chapter 55).⁹²

The GP IIb/IIIa antagonists have demonstrated similar or increased efficacy in the setting of PCI in patients with diabetes compared with nondiabetic patients, both in stable and unstable coronary disease. In view of the relatively small sample sizes of diabetic patients participating in the reported studies, however, the power to fully evaluate

whether a treatment interaction with diabetes exists is limited, and the most recent PCI guidelines do not differentiate recommendations for the use of GP IIb/IIIa antagonists according to diabetes status.⁹²

Coronary Artery Bypass Grafting

Most studies comparing outcomes in diabetic and nondiabetic patients undergoing coronary artery bypass grafting (CABG) show an increased risk of postoperative death and 30-day and long-term mortality and an increased need for subsequent reoperation in the diabetic population.^{92,93} Although diabetic patients have a worse risk profile, tend to be older, and have more extensive coronary artery disease and poorer left ventricular function in comparison with nondiabetic patients, their higher long-term mortality does not depend entirely on these factors and continues to diverge from that of nondiabetic patients during long-term follow-up, a difference that probably reflects accelerated disease progression in both bypassed and untreated coronary vessels.

Perioperative Glucose Control

The usefulness of intensive glucose control for the improvement of outcomes among patients undergoing cardiac surgery has been extensively studied, including assessment of longitudinal cohort studies and randomized trial comparisons.^{94,95} The Society of Thoracic Surgeons has published updated guideline recommendations for the perioperative glucose management of patients undergoing cardiac surgery, advocating insulin infusions for patients with or without diabetes to maintain glucose at 180 mg/dL or below, with a more stringent target of 150 mg/dL or less advocated for those patients with anticipated ICU stays exceeding 3 days.⁹⁴

Coronary Artery Bypass Grafting versus Percutaneous Coronary Intervention

In general, randomized trials comparing PCI and CABG have reported similar outcomes. In patients with diabetes, however, CABG yields superior mortality outcomes compared with PCI, with incremental benefit associated with increasing severity of underlying coronary artery disease.^{90,91} This interaction of the mode of revascularization with diabetes status emerged first from the Bypass Angioplasty Revascularization Investigation (BARI) trial, which compared balloon angioplasty with bypass surgery in patients with multivessel coronary disease (see Chapter 54). Whereas the outcomes were comparable in the overall trial and in the subset of patients without diabetes, patients with diabetes had a significantly lower mortality in the bypass arm than in those undergoing angioplasty (19% versus 34%; $P < 0.003$), prompting a NHLBI clinical alert advocating CABG over angioplasty for all such diabetic patients. Subsequently, despite the widespread availability of drug-eluting stents and other advances in devices, techniques, and adjunctive pharmacotherapy, the mortality benefit of CABG over PCI remains, as most clearly demonstrated in the Future Revascularization Evaluation in Patients with Diabetes Mellitus: Optimal Management of Multivessel Disease (FREEDOM) randomized trial.⁹⁶ In FREEDOM, 1900 patients with type 2 diabetes and obstructive multi-vessel coronary artery disease were randomized to multivessel PCI using drug-eluting stents and protocol-prescribed contemporary adjunctive therapies versus CABG. Over a median follow-up period of 3.8 years, CABG versus PCI was associated with a statistically significant reduction in a 5-year Kaplan-Meier estimate for the primary composite of time to first event of all-cause mortality, MI, and stroke (18.7% versus 26.6%; $P = 0.005$). In component analyses, CABG was associated with significantly lower risk for MI ($P = 0.001$) and death ($P = 0.049$), but with statistically increased risk for stroke (2.4 versus 5.2%; $P = 0.03$). Therefore CABG continues to be recommended as the preferred mode of revascularization for patients with diabetes and multivessel coronary disease, although the incremental risk for nonfatal stroke associated with CABG merits consideration in determining the optimal strategy for revascularization.^{92,93,96}

Revascularization Versus Optimal Medical Therapy

The BARI 2D trial randomly assigned 2368 patients with type 2 diabetes and obstructive coronary artery disease to receive prompt

revascularization plus intensive medical therapy for CVD risk reduction, or to intensive medical therapy alone.⁷⁰ The mode of revascularization was left to the discretion of the treating physician and was determined before randomization, with randomization stratified by the planned mode of revascularization. During 5 years of study follow-up, the overall mortality rates between the two groups did not differ significantly—11.7% in those undergoing revascularization, and 12.2% in those treated with intensive medical therapy alone ($P = 0.97$). In secondary analyses stratified according to the mode of revascularization, all cardiovascular outcomes were statistically similar between the PCI and medical therapy groups, but CABG compared with medical therapy was associated with a significant reduction in major adverse cardiovascular events (22.4% versus 30.5%; $P = 0.01$). These data provide support for an initial strategy of intensive medical therapy and additionally suggest the benefit of bypass surgery, although direct comparisons between PCI and CABG are not possible from this study design.

Applying Coronary Heart Disease Risk Reduction to Clinical Practice

Although myriad lifestyle and pharmacologic interventions can lessen the CVD risk of diabetes in chronic and acute settings, clinical use of such therapies remains suboptimal, probably contributing to a portion of the excess CVD risk associated with diabetes. Systematic application of global CVD risk modification to patients with diabetes measurably improves CVD outcomes (see also Chapter 42). For example, in a large registry study in Germany, total hospital mortality rate in diabetic patients hospitalized for MI declined from 29% in 1999 to 17% in 2001, and risk of death within 24 hours of admission fell from 16% to 4% during the same period.⁹⁷ This reduction was associated with the increased use of specific therapeutic approaches (e.g., coronary angiography, stenting, antiplatelet therapy) in diabetic patients during this period. Similarly, in the chronic stable population, in a randomized trial comprising a cohort of patients with diabetes and increased CVD risk defined by the presence of albuminuria, an intensive strategy of global CVD risk modification (including intensive lifestyle, glucose, lipid, and blood pressure interventions) reduced major CVD events by 50% compared with usual care.⁹⁸

Although much of the gap between the outcomes evidence and its clinical application remains poorly understood, some contributing factors may pertain. For example, patients with diabetes commonly have been denied beta blockers because of metabolism-related concerns as described previously, although outcomes trials have demonstrated clinical benefits of beta blockers among diabetes cohorts similar to or exceeding those observed in the nondiabetic population. Underuse of antiplatelet and anticoagulant therapies has been attributed to concerns for increased risk for retinal hemorrhage, yet clinical trials have not borne out these concerns. Therefore continued diligence regarding the application of evidence-based therapies with proven benefit in the diabetic population remains a key public health imperative.

HEART FAILURE IN THE PATIENT WITH DIABETES

Scope of the Problem

Although MI and hypertension are the most common risk factors associated with HF, diabetes mellitus and measures of insulin resistance before the development of diabetes also are strong and independent risk factors for HF, with an associated two- to fivefold increased risk (see Chapters 22 to 25). In addition, once HF is present, diabetes portends an especially adverse prognosis for subsequent morbidity and mortality, with estimates of relative increases in mortality hazard ranging from 30% to 60% based on subanalyses of data from a series of randomized clinical trials.^{13,99,100} In view of these observations, improved understanding of the pathobiologic underpinnings linking diabetes with HF and optimization of

TABLE 61-8 Pathophysiologic Abnormalities Associated with Cardiac Dysfunction, Congestive Heart Failure, and Adverse Outcomes in Diabetes

Sympathetic nervous system activation
Renin-angiotensin-aldosterone system activation
Increased sodium and free water retention
Decreased vascular compliance
Elevated endothelin levels (in diabetes)
Loss of “dipping” nocturnal blood pressure pattern
Increased free fatty acid levels
Dysregulated myocardial glucose and fatty acid metabolism
Increased left ventricular hypertrophy or mass via myocyte hypertrophy
Deposition of advanced glycation end products in extracellular matrix
Increased cardiac fibrosis
Increased cardiac steatosis

strategies for the prevention and treatment of HF in this population remain key public health considerations.

Mechanistic Considerations

Diabetic and nondiabetic subjects share common causes of HF, such as ischemic heart disease, hypertension, left ventricular hypertrophy, atrial fibrillation, and valvular disease. Yet, these common risk factors do not account completely for the incremental HF risk with diabetes, suggesting increased myocardial vulnerability in the setting of diabetes and probable synergistic effects between such factors and diabetes that increase HF risk, yielding the concept of “diabetic cardiomyopathy.” The pathologic underpinnings of abnormal cardiac structure and function in diabetes remain poorly understood¹³ (Table 61-8).

Ischemic Heart Disease and Hypertension

In view of its high prevalence among patients with diabetes, ischemic heart disease remains the principal risk factor for HF in these patients both in the chronic ambulatory setting and after ACS events. In addition to the burden of coronary atherosclerosis, other contributors to this increased risk may include increased prevalence of silent or atypical symptoms of ischemia delaying diagnosis and intervention, suboptimal use of therapeutic interventions, disturbed sympathovagal balance, prothrombotic milieu that may attenuate benefit of antithrombotic therapies, impaired coronary endothelial function, and disordered ischemic myocardial metabolism.¹³ In aggregate, these effects and others probably increase ischemic burden, increase infarct size, and adversely affect remodeling in the setting of ischemic heart disease and ACS events. Affecting both ischemic heart disease and HF risk, hypertension prevalence exceeds 70% in populations with diabetes. Among patients with type 2 diabetes, HF risk increases 12% for every increment of 10 mm Hg in systolic blood pressure (see Fig. 61-6).³³

Myocardial Metabolism and Structure

The direct effects of hyperglycemia and insulin resistance on myocardial cellular metabolism may contribute to cardiac dysfunction in diabetes,¹³ with altered energy substrate supply and impairment of metabolic substrate switching under conditions of stress (see Chapter 21). The myocardium uses predominantly free fatty acids under aerobic conditions, but increasingly shifts to glycolysis and pyruvate oxidation during ischemia¹³ (Fig. 61-10). In the diabetic heart, insulin resistance impairs such substrate switching and glucose transport into cells, resulting in anaerobic fatty acid oxidation and compromising the

efficiency of myocardial energetics, as well as generating pernicious oxidative byproducts. Systemic free fatty acid excess, combined with cellular dysregulation of lipid metabolism in type 2 diabetes, contributes to the accumulation of myocellular triglyceride (myocardial steatosis), resulting in further perturbations of myocyte metabolism and inducing apoptosis due to lipotoxicity, in addition to the adverse influence of cardiac mechanical function attributable to the increased myocardial mass.¹⁰¹

Diabetes causes a variety of morphologic changes in the myocardium, with abnormalities in myocytes, extracellular matrix, and microvasculature.¹³ Whereas such abnormalities are commonly present across causes of cardiomyopathy, they tend to be more common and more severe in the setting of diabetes. In addition, more specific to diabetes, the myocardial accumulation of advanced glycation end products (AGEs) (including macromolecules non-enzymatically modified by glucose), the formation and accumulation of which depend on the severity of hyperglycemia—may contribute to HF risk. Deposition of AGEs within the myocardial extracellular matrix adversely affects both systolic and diastolic cardiac function, largely attributable to AGE cross-linking of matrix collagen.

Prevention and Management of Heart Failure in Diabetes

The goals of prevention and treatment of HF in diabetic patients resemble those in nondiabetic patients: preservation of myocardial function, relief of pulmonary congestion, slowing of the progression of the disease, and prolongation of survival. In general, drug therapies for HF evaluated in the overall population of patients with risk and disease generally have similar if not better efficacy in patients with diabetes compared with those without diabetes (see Chapter 25).⁹⁹

Modulation of the Renin-Angiotensin-Aldosterone System

Meta-analysis of the effect of ACE inhibitors for primary prevention of HF in high-risk cohorts of patients with diabetes demonstrates an 18% relative risk reduction (HR, 0.82 [95% CI, 0.69 to 0.98]).³¹ Likewise, in a meta-analysis of trials comprising patients with moderate to severe systolic dysfunction, use of ACE inhibitors was associated

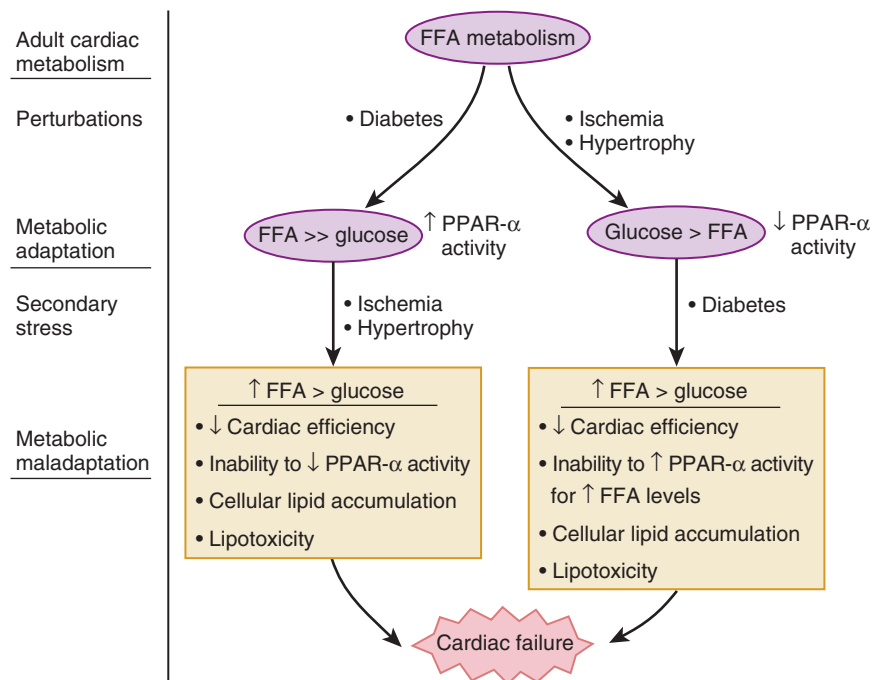

FIGURE 61-10 Schematic summary of cardiac adaptive and maladaptive metabolic modifications occurring in response to diabetes with or without superimposed ischemia or hypertrophy, culminating in overt cardiomyopathy. FFA = free fatty acid. (From Saunders J, Mathewkutty S, Drazner MH, McGuire DK: *Cardiomyopathy in type 2 diabetes: Update on pathophysiological mechanisms*. Herz 33:184, 2008.)

with a significant mortality benefit among patients with diabetes compared with placebo (RR, 0.84 [95% CI, 0.7 to 1.0])¹⁰²—numerically similar to that observed among patients in the nondiabetic group. ACE inhibitors therefore should be first-line agents for the prevention and treatment of HF in patients with diabetes.

More limited data are available on the effectiveness of ARBs for the prevention and treatment of HF among patients with diabetes. In the context of primary prevention of HF in patients with diabetes, in a meta-analysis of placebo-controlled trials, use of ARBs was associated with significant reduction for incident HF commensurate with the treatment effect observed with ACE inhibitors (HR, 0.70 [95% CI, 0.59 to 0.83]).³⁴ In the treatment of patients with prevalent HF, the data for ARBs are less consistent. On the basis of accumulated data, ARBs may be considered alternatives to ACE inhibitors for the prevention and treatment of HF,¹⁰⁰ with the most rigorous data on HF prevention obtained for losartan, and with proven effectiveness of both candesartan and valsartan in the setting of prevalent HF with decreased ejection fraction.

The effect of aldosterone antagonists (e.g., spironolactone and eplerenone) in patients with diabetes and systolic HF has not been extensively studied. In the EPHESUS randomized trial in post-MI patients, superior efficacy of eplerenone was observed in the diabetes subset of 2122 patients, similar to that in the overall trial. On the basis of these results, eplerenone is recommended for all patients with diabetes and acute MI with decreased ejection fraction, except in the presence of contraindications such as renal insufficiency or hyperkalemia, as described earlier.^{41,71}

Beta-Adrenergic Blocking Agents

Beta blockers and diuretic medications significantly reduce incident HF among patients with diabetes.³⁴ In addition, some beta blockers—including metoprolol succinate, carvedilol, and bisoprolol—have demonstrated benefit in the setting of HF with systolic dysfunction (see Chapter 25), and these effects appear to be similar independent of diabetes status.^{99,102} Carvedilol may offer advantages in diabetic patients because of its favorable effects on insulin sensitivity and plasma lipid profiles, but the clinical relevance of these observations remains uncertain. In summary, all beta blockers proven effective in the treatment of HF appear to yield similar effects in patients with diabetes.¹⁰⁰

Glucose Management

Poor glycemic control is associated with risk of HF in diabetes, with the association stronger in women than in men. Whether dysglycemia is causal or simply an associated marker of underlying CVD risk remains to be elucidated.¹⁰³ No trials to date have rigorously assessed the effect of targeting glucose control to any specific therapeutic levels, or the comparative effect of existing therapies alone or in combination with regard to their influence on major adverse HF events. Therefore the role of glucose control in the prevention and treatment of HF remains poorly understood, and pending further data, patients with diabetes and HF should be treated to achieve the recently liberalized HbA1c target of less than 8% endorsed for patients with recognized CVD.^{16,22}

Some specific considerations warrant attention with regard to drugs and strategies used to treat hyperglycemia in the setting of HF.⁵¹ Drugs with a propensity to precipitate hypoglycemia, especially sulfonylureas and exogenous insulin administration, should be used with some caution, as the stress response to hypoglycemia stimulates the neurohormonal axis implicated in the clinical complications of HF. Thiazolidinedione medications have a propensity to increase plasma volume and to precipitate incident or worsening HF; their use requires caution in patients with any degree of HF, and they are contraindicated in patients with NYHA class III or IV HF.⁵⁵ Although the modulators of the incretin axis that have most recently come to clinical use, including incretin mimetics and DPP-4 inhibitors, appear to have some favorable effects on a variety of intermediate markers associated with myocardial dysfunction and HF, research and clinical experience remain limited with regard to their overall safety and efficacy in cardiovascular cohorts, including patients at risk for HF or with overt HF.⁵¹

Although metformin historically was thought to be contraindicated in the setting of HF, those product cautions were removed in 2006 on the basis of no incremental risk for lactic acidemia in a meta-analysis of all comparative data,⁵² as well as observational studies in populations with HF yielding no signal of lactic acidosis risk and suggesting net clinical benefit. The product label did retain a caution for use specifically in the setting of acute or decompensated HF.⁵¹ The best available evidence supports consideration of the use of metformin in patients with stable and compensated HF, especially in the context of the available CVD outcomes data, low risk of hypoglycemia, low cost, and favorable tolerability profile.

Insulin therapy remains an option in patients who fail to achieve benefit with conventional oral glucose-lowering therapies, although some concern persists based on the plausibility that insulin may exacerbate signs and symptoms of HF by increasing renal sodium reclamation, contributing to increased intravascular volume.⁵¹ In the ORIGIN trial, patients randomly assigned to receive insulin glargine versus usual care tended to have fewer hospitalizations for HF, although this difference was not statistically significant (4.9% versus 5.5%; $P = 0.16$).⁵⁸ These observations from a large randomized trial analyzing 653 adjudicated HF hospitalization events support the probability that epidemiologic associations of worse outcomes in patients with HF treated with insulin result from confounding by indication, rather than from a pernicious effect of insulin per se, and challenge the concept that insulin may be detrimental because of its effects on sodium handling. Therefore, in patients with HF who fail to achieve acceptable HbA1c targets with oral agents, insulin remains an acceptable option.

In summary, HF is common among patients with diabetes, and in addition to usual pathologic contributors to HF in common with the overall population, numerous metabolic and pathologic abnormalities associated with diabetes may explain the increased HF risk and inform drug development efforts toward new therapeutic targets. Although the safety and efficacy of drugs and strategies of glucose control in patients with HF remain uncertain, the bulk of the evidence accumulated for the broader therapeutic arsenal for HF treatment in the overall population suggests that patients with diabetes derive at least as much benefit (and often more) from such evidence-based therapies. Accordingly, in addition to ongoing research in this area, clinical efforts should focus on the optimal application of existing risk-mitigating therapies in patients with diabetes and HF.

SUMMARY AND FUTURE PERSPECTIVES

Overall, diabetes increases risk for virtually all CVD complications and, most notably, atherosclerotic vascular disease and HF. Virtually all of the advances in the care of patients at risk for CVD complications during the past few decades apply to patients with diabetes, with similar or even greater benefit in this high-risk population. Nonetheless, the gradient of risk associated with diabetes persists. Further progress requires continued efforts in two domains: First, increased and optimal application of the existing evidence for CVD risk reduction is of paramount importance, with studies consistently demonstrating a substantial gap between the accumulated evidence and its application in patients with diabetes. Second, continued investigation into specific therapies and strategies targeting the unique risks for CVD associated with diabetes remains a critical global public health imperative. In that light, driven largely by the regulatory evolution toward requiring CVD safety and efficacy evaluations for all drugs developed for diabetes management, a proliferation of randomized CVD clinical outcomes trials currently are under way or in development, providing great promise for the future management of diabetic CVD.

ACKNOWLEDGMENT

The author gratefully acknowledges the contributions of Dr. Richard W. Nesto to previous versions of this chapter in earlier editions of this text.

GUIDELINES

Diabetes and Heart Disease

Darren K. McGuire

Recommendations for the management of patients with diabetes appear in various guidelines and scientific statements from the American College of Cardiology Foundation (ACCF)/AHA, the European Society of Cardiology (ESC), and other cardiovascular societies; from the ADA, EASD, and other endocrinologic societies; and from the National Cholesterol Education Program—Adult Treatment Panel and Joint National Committee, among others. Principal among these publications are dedicated scientific statements, developed by the ACCF/AHA in collaboration with the ADA, focused on the care of patients with diabetes for the primary prevention of CVD,¹ the management of hyperglycemia for hospitalized patients,² and the use of aspirin for primary prevention of CVD complications.³ In addition, diabetes-specific guidance appears in ACCF/AHA guidelines for the management of non-ST-segment elevation myocardial infarction (NSTEMI)⁴ and ST-segment elevation myocardial infarction (STEMI),⁵ and the management of patients with HF. Similar guidance has been incorporated in the ESC guidelines for these disease conditions that largely parallels the ACCF/AHA recommendations, with additional comments included when the recommendations differ between these professional societies. Finally, the ADA provides recommendations for the global management of patients with diabetes including but extending well beyond cardiovascular issues in the “Standards of Medical Care in Diabetes,”⁶ updated annually—a breadth of guidance

well beyond the scope of this chapter, and specific guidance in collaboration with the EASD on chronic glucose management targets and strategies.

PRIMARY AND SECONDARY PREVENTION OF CARDIOVASCULAR DISEASE

Therapeutic Lifestyle Counseling

Therapeutic Lifestyle Counseling (TLC) interventions are the cornerstone for the treatment of all patients with diabetes, including counseling for regular physical activity, nutritional counseling for weight management and healthy food choices, and counseling for smoking abstinence.^{1,6,7} Medical nutrition therapy should be targeted at caloric restriction for weight management, with limited fat intake (<30% of daily energy; <7% from saturated fats) and increased dietary fiber intake recommended. Leisure time physical activity targets are at least 150 minutes weekly of modest-intensity exercise, or at least 90 minutes weekly of vigorous exercise. Beyond these, specific recommendations are available for the treatment of other cardiovascular risk factors, with the ACCF/AHA recommendations summarized in **Table 61G-1**.

Lipids (see also the Guidelines section to **Chapter 42** regarding updated lipid guidelines)

Lipid profiles should be obtained in all adults with diabetes.^{1,6,7} As an adjunct to TLC interventions, the primary treatment for dyslipidemia

**TABLE 61G-1 ACCF/AHA Recommendations for Primary Prevention of Cardiovascular Disease in People with Diabetes****Lifestyle Management****Weight**

Structured programs that emphasize lifestyle changes such as reduced fat (<30% of daily energy) and total energy intake and increased regular physical activity, along with regular participant contact, can produce long-term weight loss on the order of 5% to 7% of starting weight, with improvement in blood pressure.

For persons with elevated plasma triglycerides and reduced HDL cholesterol, improved glycemic control, moderate weight loss (5% to 7% of starting weight), dietary saturated fat restriction, increased physical activity, and modest replacement of dietary carbohydrate (5% to 7%) by either monounsaturated or polyunsaturated fats may be beneficial.

Medical Nutrition Therapy

To achieve reductions in LDL cholesterol:

Saturated fats should be <7% of energy intake.

Dietary cholesterol intake should be <200 mg/d. Intake of *trans*-unsaturated fatty acids should be <1% of energy intake.

Total energy intake should be adjusted to achieve body weight goals.

Total dietary fat intake should be moderated (25% to 35% of total calories) and should consist mainly of monounsaturated or polyunsaturated fat.

Ample intake of dietary fiber (≥ 14 g/1000 calories consumed) may be of benefit.

If individuals choose to drink alcohol, daily intake should be limited to one drink for adult women and two drinks for adult men. One drink is defined as a 12-oz beer, a 4-oz glass of wine, or a 1.5-oz glass of distilled spirits. Alcohol ingestion increases caloric intake and should be minimized when weight loss is the goal.

Individuals with elevated plasma triglyceride levels should limit intake of alcohol, because it may exacerbate hypertriglyceridemia.

In both normotensive and hypertensive persons, a reduction in sodium intake may lower blood pressure. The goal should be to reduce sodium intake to 1200 to 2300 mg/day (50 to 100 mmol/day), equivalent to 3000 to 6000 mg/day of sodium chloride.

Physical Activity

To improve glycemic control, assist with weight loss or maintenance, and reduce risk of CVD, at least 150 minutes of moderate-intensity aerobic physical activity or at least 90 minutes of vigorous aerobic exercise per week is recommended. The physical activity should be distributed over at least 3 days per week, with no more than 2 consecutive days without physical activity.

For long-term maintenance of major weight loss, a larger amount of exercise (7 hours of moderate or vigorous aerobic physical activity per week) may be helpful.

Blood Pressure

Blood pressure should be measured at every routine diabetes visit. Patients found to have systolic blood pressure ≥ 130 mm Hg or diastolic blood pressure ≥ 80 mm Hg should have blood pressure confirmed on a separate day.

Patients with diabetes should be treated to achieve a systolic blood pressure (SBP) at least < 140 mm Hg and a diastolic blood pressure (DBP) < 90 mm Hg, and for patients who can tolerate without adverse symptoms, can target as low as SBP < 130 and DBP < 80. Patients with a systolic blood pressure of 130 to 139 mm Hg or a diastolic blood pressure of 80 to 89 mm Hg should initiate lifestyle modification alone (weight control, increased physical activity, alcohol moderation, sodium reduction, and emphasis on increased consumption of fresh fruits, vegetables, and low-fat dairy products) for a maximum of 3 months. If, after these efforts, targets are not achieved, treatment with pharmacologic agents should be initiated.

Patients with hypertension (systolic blood pressure ≥ 140 mm Hg or diastolic blood pressure ≥ 90 mm Hg) should receive drug therapy in addition to lifestyle and behavioral therapy.

All patients with diabetes and hypertension should be treated with a regimen that includes either an ACE inhibitor or an ARB. If one class is not tolerated, the other should be substituted. Other drug classes demonstrated to reduce CVD events in patients with diabetes—beta blockers, thiazide diuretics, and calcium channel blockers—should be added as needed to achieve blood pressure targets.

If ACE inhibitors, ARBs, or diuretics are used, renal function and serum potassium levels should be monitored within the first 3 months. If blood pressure is stable, follow-up could occur every 6 months thereafter.

Multiple-drug therapy generally is required to achieve blood pressure targets.

In elderly hypertensive patients, blood pressure should be lowered gradually to avoid complications.

Orthostatic measurement of blood pressure should be performed in people with diabetes and hypertension when clinically indicated.

Patients not achieving target blood pressure despite multiple-drug therapy should be referred to a physician specializing in the care of patients with hypertension.

Lipids

In adult patients, lipid levels should be measured at least annually and more often if needed to achieve goals. In adults younger than 40 years of age with low-risk lipid values (LDL cholesterol < 100 mg/dL, HDL cholesterol > 50 mg/dL, and triglycerides < 150 mg/dL), lipid assessments may be repeated every 2 years.

Lifestyle modification deserves primary emphasis in all diabetic individuals. Patients should focus on the reduction of saturated fat and cholesterol intake, weight loss (if indicated), and increases in dietary fiber and physical activity. These lifestyle changes have been shown to improve the lipid profile in patients with diabetes. In persons with diabetes who are older than 40 years of age, without overt CVD but with one or more major CVD risk factors, the primary goal is a LDL cholesterol level < 100 mg/dL (2.6 mmol/L). If LDL-lowering drugs are used, a reduction of at least 30% to 40% in LDL cholesterol levels should be obtained.

If baseline LDL cholesterol is < 100 mg/dL, statin therapy should be initiated based on risk factor assessment and clinical judgment. Major risk factors in this category include cigarette smoking, hypertension (blood pressure > 140/90 mm Hg or use of antihypertensive medication), low HDL cholesterol (<40 mg/dL), and family history of premature CHD (CHD in male first-degree relative ≤ 55 years of age; CHD in female first-degree relatives ≤ 65 years of age).

In people with diabetes who are younger than 40 years of age, without overt CVD, but who are estimated to be at increased risk for CVD either by clinical judgment or by risk calculator, the LDL cholesterol goal is <100 mg/dL, and LDL-lowering drugs should be considered if lifestyle changes do not achieve the goal.

The ADA and AHA suggest different approaches to the management of HDL- and triglyceride-associated CVD risk.

The AHA suggests that in patients with triglyceride levels of 200 to 499 mg/dL, a non-HDL cholesterol (total cholesterol minus HDL cholesterol) goal of ≤ 130 mg/dL is a secondary target. If triglycerides are ≥ 500 mg/dL, therapeutic options include fibrates or niacin before LDL-lowering therapy and treatment of LDL cholesterol to goal after triglyceride-lowering therapy. A non-HDL cholesterol level ≤ 130 mg/dL should be achieved if possible.

The ADA suggests lowering triglycerides to <150 mg/dL (1.7 mmol/L) and raising HDL cholesterol to >40 mg/dL (1.15 mmol/L). In women, a HDL goal 10 mg/dL higher (>50 mg/dL) should be considered.

Combination therapy with LDL-lowering drugs (e.g., statins) and fibrates or niacin may be necessary to achieve lipid targets, but this strategy has not been evaluated in outcomes studied for either CVD event reduction or safety.

Continued

TABLE 61G-1 ACCF/AHA Recommendations for Primary Prevention of Cardiovascular Disease in People with Diabetes—cont'd**Tobacco**

All patients with diabetes should be asked about tobacco use status at every visit.
 Every tobacco user should be advised to quit.
 The tobacco user's willingness to quit should be assessed.
 The patient can be assisted by counseling and by developing a plan to quit.
 Follow-up, referral to special programs, or pharmacotherapy (including nicotine replacement and bupropion) should be incorporated as needed.

Antiplatelet Agents

Aspirin therapy (75 to 162 mg/day) should be recommended as a primary prevention strategy in those with diabetes at increased cardiovascular risk, including those who are older than 40 years of age or who have additional risk factors (family history of CVD, hypertension, smoking, dyslipidemia, or albuminuria).
 People with aspirin allergy, bleeding tendency, existing anticoagulant therapy, recent gastrointestinal bleeding, and clinically active hepatic disease are not candidates for aspirin therapy. Other antiplatelet agents may be a reasonable alternative for patients with high risk.
 Aspirin therapy should not be recommended for patients younger than 21 years of age because of the increased risk of Reye syndrome associated with aspirin use in this population. People younger than 30 years have not been studied.

Glycemic Control

The A1c goal for patients in general is <7%.
 The A1c goal for the individual patient is an A1c level as close to normal (<6%) as possible, without causing significant hypoglycemia.

Type 1 Diabetes Mellitus

At present, all of the recommendations listed above for patients with type 2 diabetes mellitus appear to be appropriate for those with type 1 diabetes as well.

From Buse JB, Ginsberg HN, Bakris GL, et al: Primary prevention of cardiovascular diseases in people with diabetes mellitus: A scientific statement from the American Heart Association and the American Diabetes Association. *Circulation* 115:114, 2007.

is statin therapy,^{1,6,7} with combination therapy reserved for those patients not tolerating statin therapy, acknowledging the limited outcomes data available to support the efficacy of any of the presently available add-on therapies. Statin medications should be prescribed for all patients with diabetes between ages 40 and 75 with LDL cholesterol levels between 70 and 189 mg/dL.^{1,7,8} At present no medical therapies are recommended to specifically target treatment of low HDL cholesterol or high triglyceride, and no consensus has been reached nor are compelling data available to endorse any one additional therapy over another for this purpose, with options including ezetimibe, bile acid binders, fish oil, fibrates, and niacin.^{6,7}

Blood Pressure

Blood pressure should be measured at every clinical encounter in patients with diabetes.¹ All patients with diabetes should be treated to a target of no more than 140/80 mm Hg, with a more intensive target of below 130/80 mm Hg for those who can achieve it without side effects or undue clinical burden of therapy.⁶ TLC interventions including physical activity, weight management, and dietary sodium restriction form the cornerstone for the management of hypertension. ACE inhibitors should be used as the primary antihypertensive therapy in the absence of contraindications or intolerance, or alternatively, ARBs can be used in persons who experience cough, rash, or angioedema on ACE inhibitors. Other drug classes should be added as needed to achieve therapeutic targets, with thiazide diuretics, dihydropyridine calcium channel blockers, and beta blockers preferred based on an evidence basis of CVD risk reduction in populations with diabetes.¹

Aspirin

Daily aspirin therapy is recommended for patients with diabetes, older than 50 years of age for men and older than 60 years of age for women, in the setting of one or more additional CVD risk factors. The dose of aspirin recommended is 75 to 162 mg daily.^{6,9}

Glucose Management

In general, a HbA1c target of below 7% is recommended for most patients with diabetes.^{1,6} More recent guidance from the ADA/EASD

endorses a more personalized approach to determination of the most appropriate HbA1c targets based on patient and drug characteristics, with the consideration of more intensive control for younger patients, shorter duration of diabetes, and/or fewer comorbid conditions, and more liberal HbA1c targets for higher-risk patients.^{6,10} In addition to TLC, metformin is recommended for all patients with type 2 diabetes in the absence of contraindication or intolerance, with the addition of other therapies left to the discretion of the care provider.¹⁰

In general, guidelines for the management of secondary CVD prevention are similar for patients with and without diabetes. Diabetes-specific recommendations for secondary prevention are summarized in **Table 61G-2**.¹¹

ACUTE CORONARY SYNDROMES

With few exceptions, the management of patients with unstable angina or NSTEMI (UA/NSTEMI) and STEMI should be similar to that of patients without diabetes.^{4,5,12} Diabetes-specific recommendations are summarized in **Table 61G-3**. In general, the recommendations unique to the diabetes population focus on an increased level of evidence for ACE inhibitors for all patients and aldosterone antagonists for those with LVEF less than 40%, with or without clinical HF; a higher level of recommendation for the adjunctive use of GP IIb/IIIa antagonists for patients with UA/NSTEMI; and preferential use of CABG over PCI for patients with more extensive coronary artery disease (CAD), independent of LV systolic function. In addition, recommendations provide guidance for the use of insulin for targeted glucose control, noting a substantial evolution from the original guidelines in 2004 and 2007 that advocated normal or near-normal glucose target levels,^{4,13} to the present targets of permissive hyperglycemia, reserving insulin only to maintain blood glucose below 180 mg/dL.^{5,12}

Coronary Revascularization

For patients requiring coronary revascularization, patients with diabetes have been among the most controversial population with regards to the merits of PCI versus CABG. The most recent ACCF/AHA/SCAI (Society for Cardiac Angiography and Interventions) guidelines

TABLE 61G-2 ACCF/AHA Recommendations for Secondary Prevention of Cardiovascular Disease in People with Diabetes

CLASS	INDICATION	LEVEL OF EVIDENCE
I	Care for diabetes should be coordinated with the patient's primary care physician and/or endocrinologist.	C
	Lifestyle modifications including daily physical activity, weight management, blood pressure control, and lipid management are recommended for all patients with diabetes.	B
	ACE inhibitors should be started and continued indefinitely in patients with diabetes, unless contraindicated.	A
	Use of aldosterone blockade in post-MI patients without significant renal dysfunction or hyperkalemia is recommended in patients who are already receiving therapeutic doses of an ACE inhibitor and beta blocker, who have a left ventricular ejection fraction $\leq 40\%$ and diabetes.	A
IIa	Metformin is an effective first-line pharmacotherapy and can be useful if not contraindicated.	A
	Individualizing the intensity of blood sugar-lowering interventions based on the individual patient's risk of hypoglycemia during treatment is reasonable.	C
IIb	Initiation of pharmacotherapy interventions to achieve target HbA1c may be reasonable.	A
	A target HbA1c of $\leq 7\%$ may be considered.	C
	Less stringent HbA1c goals may be considered for patients with a history of severe hypoglycemia, limited life expectancy, advanced microvascular or macrovascular complications, or extensive comorbidity, or those in whom the goal is difficult to attain despite intensive therapeutic interventions.	C

From Smith SC Jr, Benjamin EJ, Bonow RO, et al: AHA/ACC secondary prevention and risk reduction therapy for patients with coronary and other atherosclerotic vascular disease: 2011 update: A guideline from the American Heart Association and American College of Cardiology Foundation. *Circulation* 124:2458, 2011.

TABLE 61G-3 ACCF/AHA Recommendations for the Management of Unstable Angina/Non-ST-Segment Elevation Myocardial Infarction (UA/NSTEMI) and of ST-Segment Elevation Myocardial Infarction (STEMI) in Patients with Diabetes^{4,5,12}

CLASS	INDICATION	LEVEL OF EVIDENCE
UA/NSTEMI		
I	ACE inhibitors should be given and continued indefinitely for patients recovering from UA/NSTEMI with diabetes unless contraindicated.	A
	Long-term aldosterone receptor blockade should be prescribed for patients with UA/NSTEMI without significant renal dysfunction (estimated creatinine clearance should be greater than 30 mL/min) or hyperkalemia (potassium should be <5 mEq/L) who are already receiving therapeutic doses of an ACE inhibitor, have an EF $< 40\%$, and have diabetes, with or without clinical heart failure.	A
IIa	Use of an insulin-based regimen to achieve and maintain glucose levels less than 180 mg/dL while avoiding hypoglycemia for hospitalized patients with UA/NSTEMI, with either a complicated or uncomplicated course, is reasonable.	B
	For patients with UA/NSTEMI and multivessel disease, CABG using the internal mammary arteries can be beneficial over PCI in patients with medically treated diabetes.	B
IIb	PCI is reasonable for UA/NSTEMI patients with diabetes with single-vessel disease and inducible ischemia.	B
	The use of upstream GP IIb/IIIa inhibitors may be considered in UA/NSTEMI patients with diabetes already receiving aspirin and a P2Y ₁₂ receptor inhibitor (clopidogrel, prasugrel, or ticagrelor) who are selected for an invasive strategy and are not otherwise at high risk for bleeding.	B
STEMI		
I	An aldosterone antagonist should be given to patients with STEMI and no contraindications who are already receiving an ACE inhibitor and beta blocker and who have an EF $\leq 40\%$ and have diabetes, with or without clinical heart failure.	B

for PCI have only one diabetes-specific graded recommendation—class IIb (B): CABG is probably recommended in preference to PCI to improve survival in patients with multivessel CAD and diabetes mellitus, particularly if a left internal mammary artery graft can be anastomosed to the left anterior descending artery.¹⁴

Patients with diabetes represent approximately one third of all patients undergoing PCI. In addition to this graded recommendation, for patients undergoing PCI, diabetes mellitus is among the characteristics favoring preferential use of drug-eluting stents over bare metal stents, with no clear evidence favoring any one drug-eluting stent type over others. Even with the use of drug-eluting stents, however, diabetes remains associated with significantly increased risk for in-stent restenosis. In addition, diabetes is identified as a specific risk factor for post-PCI complications including periprocedural death and the development of contrast-induced acute kidney injury, with recommendations for adequate preparatory hydration and minimization of the volume of contrast media used in such patients. Finally, in the setting of UA/NSTEMI, diabetes is among the patient characteristics favoring an early invasive management strategy.

HEART FAILURE

The diagnosis and management of HF generally are the same for patients with and without diabetes. **Table 61G-4** summarizes diabetes-specific recommendations from the most recent update of the ACCF/AHA guidelines for the diagnosis and management of HF in adults. The most recent staging system for HF¹⁵ identifies diabetes alone as HF stage A, reflecting the high risk associated with diabetes for the development of HF, with modest incremental risk in men but threefold increased risk in women for developing HF in the setting of diabetes.

Approximately one third of patients with HF have diabetes. The importance of blood pressure control, preferentially with ACE inhibitors or ARBs, is underscored for the prevention of HF in patients with diabetes. Metformin may be used in patients with stable HF with preserved renal function but should be avoided in patients with unstable HF or that necessitating hospitalization.⁶ Pioglitazone should not be initiated in patients with NYHA class III or IV HF, with caution for use in patients with any degree of HF.¹⁶

**TABLE 61G-4 ACCF/AHA Recommendations for the Diagnosis and Management of Heart Failure in Patients with Diabetes¹⁵**

CLASS	INDICATION	LEVEL OF EVIDENCE
I	For patients with diabetes mellitus (all of whom are at high risk for developing HF), blood sugar should be controlled in accordance with contemporary guidelines.	C
I	Physicians should control systolic and diastolic blood hypertension and diabetes mellitus in patients with HF in accordance with recommended guidelines.	C
IIb	ACE inhibitors can be useful to prevent HF in patients with diabetes.	A
IIb	ARBs can be useful to prevent HF in patients with diabetes.	C

This chapter has been written for practicing cardiologists and is compatible with the existing expert management recommendations¹⁻³ for the care of adult patients with congenital cardiac defects. Although concentrating on the issues of late adolescence and adulthood, such issues can be appreciated only in the setting of a comprehensive understanding of the anatomy, physiology, and events during childhood, and these issues are discussed in each section. Additional information can be found in other sources.^{4,5} *Congenital cardiovascular disease* is defined as an abnormality in cardiocirculatory structure or function that is present at birth, even if discovered much later. Congenital cardiovascular malformations usually result from altered embryonic development of a normal structure or failure of such a structure to progress beyond an early stage of embryonic or fetal development. The aberrant patterns of flow created by an anatomic defect may, in turn, significantly influence the structural and functional development of the remainder of the circulation. For example, the presence in utero of mitral atresia may prohibit normal development of the left ventricle, aortic valve, and ascending aorta. Similarly, constriction of the fetal ductus arteriosus may result in right ventricular dilation and tricuspid regurgitation in the fetus and newborn, contribute importantly to the development of pulmonary arterial aneurysms in the presence of a ventricular septal defect (VSD) and absent pulmonary valve, or result in an alteration in the number and caliber of fetal and newborn pulmonary vascular resistance vessels.

Postnatal events can markedly influence the clinical features of a specific "isolated" malformation. Infants with Ebstein malformation of the tricuspid valve may improve dramatically as the magnitude of tricuspid regurgitation diminishes with the normal fall in pulmonary vascular resistance after birth, and infants with pulmonary atresia or severe stenosis may not become cyanotic until normal spontaneous closure of a patent ductus arteriosus (PDA) takes place. Ductal constriction many days after birth may also be a central factor in some infants in the development of coarctation of the aorta. Still later in life, patients with a VSD may experience spontaneous closure and the development of right ventricular outflow tract obstruction and/or aortic regurgitation with increasing duration of follow-up. These

selected examples serve to emphasize that anatomic and physiologic changes in the heart and circulation can continue to evolve from the prenatal period to late adult life.

Incidence in Childhood. The true incidence of congenital cardiovascular malformations is difficult to determine accurately, partly because of difficulties in definition. The incidence in fetal life exceeds that in early childhood because very complex lesions are associated with early nonviability or later in utero death. Consequently, approximately 0.8% of live births are complicated by a cardiovascular malformation. This figure does not take into account what may be the two most common cardiac anomalies: a congenital, functionally normal bicuspid aortic valve and prolapse of the mitral valve.

Specific defects can have a definite sex preponderance: PDA, Ebstein anomaly of the tricuspid valve, and secundum atrial septal defect (ASD) are more common in females, whereas aortic valve stenosis, coarctation of the aorta, hypoplastic left heart syndrome, pulmonary and tricuspid atresia, and transposition of the great arteries (TGA) are more common in males.

Extracardiac anomalies occur in approximately 25% of infants with significant cardiac disease, and their presence may significantly increase mortality. The extracardiac anomalies are often multiple. One third of infants with both cardiac and extracardiac anomalies have some established syndrome.

The Adult Patient. Thanks to the great successes in pediatric cardiac care, the overall number of adult patients with congenital heart disease (CHD) is now greater than the number of pediatric cases. Indeed, more than 90% of patients born in 1990 in Belgium survived to at least 18 years of age.⁶ In the United States, 40,000 babies are born each year with congenital heart defects. More than 35,000 of them will reach 18 years of age and beyond. At present, approximately 1.3 million American adults have congenital heart defects, more than 50% of which are classified as complex and in need of life-long expert surveillance. These moderately to very complex patients are at significant risk for premature mortality, reoperation, or future complications of their conditions and their treatments. Many patients, especially those with moderately to very complex conditions, should see a specialist trained in the care of adult CHD. Currently, not enough such practitioners or facilities are available to always make this possible.

Adult patients should have been taught in adolescence about their condition, their future outlook, and the possibility of further surgery and complications if appropriate, and they also should have been advised about their responsibilities in ensuring self-care and professional surveillance. Copies of operative reports should accompany patients being transferred for adult care, along with other key documents from the pediatric file.

Table 62-1 lists the types of patients who should be considered “simple” and suitable for community care. **Tables 62-2 and 62-3** show the diagnoses for “moderately complex” and “very complex” patients. Moderately and very complex patients should be monitored throughout their lives in a specialized center.

CHD in an adult is not simply a continuation of the childhood experience. The patterns of many lesions change in adult life. Arrhythmias are more frequent and of a different character (see [Chapter 37](#)). Cardiac chambers often enlarge, and systolic dysfunction tends to develop in the ventricles. Bioprosthetic valves, prone to early failure in childhood, last longer when implanted at an older age. The comorbid conditions that tend to develop in adult life often become important factors needing attention. As a result, the needs of these adult patients with CHD are often best met by a physician or team familiar with both pediatric and adult cardiology issues. For the best results, congenital heart surgery and interventional catheterization procedures should be performed at centers with adequate surgical and

institutional volumes of congenital heart cases at any age. Patients undergoing surgery in a nonspecialist environment, even when operated on by a congenital heart surgeon, suffer threefold increased mortality in comparison to those in specialized congenital heart centers.⁷ In most cases the specialist environment is a children’s hospital, probably a nonsustainable model for optimal care as this population expands.

Echocardiographic studies, diagnostic heart catheterizations, electrophysiologic studies, magnetic resonance imaging (MRI), and other imaging of complex cases (see [Chapters 14 to 19](#)) are best done where qualified staff has relevant training, experience, and equipment. Ideally, patient care should be multidisciplinary. Special cardiology and echocardiography skills are essential, but individuals with other special training, experience, and interest should also be accessible, including congenital heart surgeons and their teams, nurses, reproductive health staff, mental health professionals, medical imaging specialists, respiratory consultants, and others.

CAUSE

Congenital cardiac malformations can occur via mendelian inheritance directly as a result of a genetic abnormality, be strongly associated with an underlying genetic disorder (e.g., trisomy), be related directly to the effect of an environmental toxin (e.g., maternal diabetes, alcohol), or result from an interaction between multifactorial genetic and environmental influences too complex to allow a single definition of cause (e.g., CHARGE syndrome [see later under [Syndromes in Congenital Heart Disease](#)]). The latter group is shrinking as genetic research identifies new genetic abnormalities underlying many conditions.

Genetic. A single gene mutation can be causative in the familial forms of ASD with prolonged atrioventricular (AV) conduction; mitral valve prolapse; VSD; congenital heart block; situs inversus; pulmonary hypertension; and the Noonan, LEOPARD, Ellis-van Creveld, and Kartagener syndromes (see [Syndromes in Congenital Heart Disease](#) later). The genes responsible for several defects have now been identified (e.g., long-QT syndrome, Holt-Oram syndrome, Marfan syndrome, hypertrophic cardiomyopathy, supraventricular aortic stenosis), and contiguous gene defects on the long arm of chromosome 22 underlie the conotruncal malformations of DiGeorge and velocardiofacial syndromes. However, at present, less than 15% of all cardiac malformations can be accounted for by chromosomal aberrations or genetic mutations or transmission (see [Chapters 32 and 33](#)).

It is interesting, but unexplained, that several different gene defects may lead to the same cardiac malformation (e.g., AV septal defect). Furthermore, the finding that with some exceptions, only one of a pair of monozygotic twins is affected by CHD indicates that most cardiovascular malformations are not inherited in a simple manner. However, this observation may in the past have led to an underestimation of the genetic contribution because most recent twin studies reveal more than double the incidence of heart defects in monozygotic twins but usually in only one of the pair. Family studies indicate a 2- to 10-fold increase in the incidence of CHD in siblings of affected patients or in the offspring of an affected parent. Malformations are often concordant or partially concordant within families. Routine fetal

TABLE 62-1 Types of Adult Patients with Simple Congenital Heart Disease*

Native Disease
Isolated congenital aortic valve disease
Isolated congenital mitral valve disease (except parachute valve, cleft leaflet)
Isolated patent foramen ovale or small ASD
Isolated small VSD (no associated lesions)
Mild pulmonic stenosis
Repaired Conditions
Previously ligated or occluded ductus arteriosus
Repaired secundum or sinus venosus ASD without residua
Repaired VSD without residua

*These patients can usually be cared for in the general medical community. From Webb G, Williams R, Alpert J, et al: 32nd Bethesda Conference: Care of the Adult with Congenital Heart Disease, October 2-3, 2000. *J Am Coll Cardiol* 37:1161, 2001.

TABLE 62-2 Types of Adult Patients with Congenital Heart Disease of Moderate Severity*

Aorto–left ventricular fistulas
Anomalous pulmonary venous drainage, partial or total
AV septal defects (partial or complete)
Coarctation of the aorta
Ebstein anomaly
Infundibular right ventricular outflow obstruction of significance
Ostium primum ASD
PDA (not closed)
Pulmonary valve regurgitation (moderate to severe)
Pulmonic valve stenosis (moderate to severe)
Sinus of Valsalva fistula/aneurysm
Sinus venosus ASD
Subvalvular or supraventricular aortic stenosis (except HOCM)
Tetralogy of Fallot
Ventricular septal defect with the following:
Absent valve or valves
Aortic regurgitation
Coarctation of the aorta
Mitral disease
Right ventricular outflow tract obstruction
Straddling tricuspid/mitral valve
Subaortic stenosis

*These patients should be seen periodically at regional adult CHD centers. AV = atrioventricular; HOCM = hypertrophic obstructive cardiomyopathy. From Webb G, Williams R, Alpert J, et al: 32nd Bethesda Conference: Care of the Adult with Congenital Heart Disease, October 2-3, 2000. *J Am Coll Cardiol* 37:1161, 2001.

TABLE 62-3 Types of Adult Patients with Congenital Heart Disease of Great Complexity*

Conduits, valved or nonvalved
Cyanotic CHD (all forms)
Double-outlet ventricle
Eisenmenger syndrome
Fontan procedure
Mitral atresia
Single ventricle (also called <i>double inlet</i> or <i>outlet</i> , <i>common</i> or <i>primitive</i>)
Pulmonary atresia (all forms)
Pulmonary vascular obstructive diseases
Transposition of the great arteries
Tricuspid atresia
Truncus arteriosus/hemitruncus
Other abnormalities of AV or ventriculoarterial connection not included above (i.e., crisscross heart, isomerism, heterotaxy syndromes, ventricular inversion)

*These patients should be seen regularly at adult CHD centers. From Webb G, Williams R, Alpert J, et al: 32nd Bethesda Conference: Care of the Adult with Congenital Heart Disease, October 2-3, 2000. *J Am Coll Cardiol* 37:1161, 2001.

cardiac screening of subsequent pregnancies should be performed in such circumstances.

Environmental. Maternal diabetes, rubella, ingestion of thalidomide and isotretinoin early during gestation, and chronic alcohol abuse are environmental insults known to interfere with normal cardiogenesis in humans. For example, the incidence of tetralogy of Fallot with pulmonary atresia is increased 10-fold in the offspring of diabetic mothers. Rubella syndrome consists of cataracts; deafness; microcephaly; and either singly or in combination, PDA, pulmonary valve and/or arterial stenosis, and ASD. Thalidomide exposure is associated with major limb deformities and, occasionally, cardiac malformations without a predilection for a specific lesion. Tricuspid valve anomalies are associated with the ingestion of lithium during pregnancy. Fetal alcohol syndrome consists of microcephaly, micrognathia, microphthalmos, prenatal growth retardation, developmental delay, and cardiac defects (often defects of the ventricular septum) in approximately 45% of affected infants.

PREVENTION

Physicians who treat pregnant women should be aware of the effects of known teratogens, as well as drugs (e.g., angiotensin-converting enzyme [ACE] inhibitors and fetal renal development), that may have a functional rather than a structural damaging influence on the fetal and newborn heart and circulation. They should also recognize that information about the teratogenic potential of many drugs is inadequate. Similarly, appropriate radiologic equipment and techniques for reducing gonadal and fetal radiation exposure should always be used to reduce the potential hazards of this potential cause of birth defects.

Detection of genetic abnormalities during fetal life is becoming an increasing reality. Fetal cells are obtained from amniotic fluid or chorionic villus biopsy. Many fetuses in whom CHD is detected will undergo genetic testing, and fetal echocardiography is frequently indicated when a chromosomal abnormality is diagnosed because of other reasons. Many social, religious, and legal considerations influence whether termination of pregnancy is performed under these circumstances, but the improved outcomes with even the most complex CHDs frequently argue against the cardiac condition being used as the sole reason. Immunization of children with rubella vaccine has been one of the most effective preventive strategies against fetal rubella syndrome and its associated congenital cardiac abnormalities.

ANATOMY

Normal Cardiac Anatomy

The key to understanding CHD is having an appreciation of the segmental approach to the diagnosis of both simple and complex lesions.

Cardiac Situs

This refers to the status of the atrial appendages. The normal left atrial appendage is a finger-like structure with a narrow base and no guarding crista. On the other hand, the right atrial appendage is broad based and has a guarding crista and pectinate muscles. *Situs solitus* or *inversus* refers to hearts with both a morphologic left and right atrium. *Situs ambiguus* refers to hearts with two morphologic left or right atrial appendages. These conditions are dealt with in the section on isomerism and have implications with regard to associated intracardiac and extracardiac abnormalities.

Atrioventricular Connections

This refers to the connections between the atria and ventricles. The AV connections are said to be concordant if the morphologic left atrium is connected to the morphologic left ventricle via the mitral valve, with the morphologic right atrium connecting to the morphologic right ventricle via a tricuspid valve. They are said to be discordant in other circumstances, such as in congenitally corrected TGA (cc-TGA), and to be univentricular when both atria connect predominantly to one of the ventricles.

Ventriculoarterial Connections

This refers to the connections between the semilunar valves and ventricles. Ventriculoarterial concordance occurs when the

morphologic left ventricle is connected to the aorta and the morphologic right ventricle is connected to the pulmonary artery. Ventriculoarterial discordance occurs when the morphologic left ventricle is connected to the pulmonary artery and the aorta is connected to the morphologic right ventricle. Double-outlet right ventricle occurs when more than 50% of both great arteries is connected to the morphologic right ventricle. A single-outlet heart has only one great artery connected to the heart.

Atria

Assignment of either a morphologic left or right atrium is determined by the morphology of the atrial appendages and not by the status of the systemic or pulmonary venous drainage. The right atrial appendage is broad and triangular, whereas the left one is smaller and finger-like. The internal architecture is the key feature to an accurate diagnosis, with the right having extensive pectinate muscles that run around the vestibule of the atrium, unlike its left counterpart. Although the pulmonary veins usually drain to a morphologic left atrium and the systemic veins drain into a morphologic right atrium, such is not always the case.

Atrioventricular Valves

The morphologic mitral valve is a bileaflet valve with the anterior or aortic leaflet in fibrous continuity with the noncoronary cusp of the aortic valve. The mitral valve leaflets are supported by two papillary muscle groups located in the anterolateral and posteromedial positions. Each papillary muscle supports the adjacent part of both valve leaflets, with considerable variation in morphology of the papillary muscles.

The tricuspid valve is a trileaflet valve, although it can frequently be difficult to identify all three leaflets because of variability in the anteroposterior commissure. With close inspection, the commissural chordae that arise from the papillary muscles may permit identification of the three leaflets. The three leaflets occupy a septal anterior, superior, and inferior position. The commissures between the leaflets are the anterior septal, anterior inferior, and inferior commissures. The papillary muscles supporting the valve leaflets arise mostly from the trabeculoseptomarginalis and its apical ramifications.

Morphologic Right Ventricle

The morphologic right ventricle is a triangular-shaped structure with inlet, trabecular, and outlet components. The inlet component of the right ventricle has attachments from the septal leaflet of the tricuspid valve. Inferior to this is the moderator band, which arises at the base of the trabeculoseptomarginalis, with extensive trabeculations toward the apex of the right ventricle. The outlet component of the right ventricle consists of a fusion of three structures (i.e., the infundibular septum separating the aortic from the pulmonary valve, the ventriculoinfundibular fold separating the tricuspid valve from the pulmonary valve, and finally the anterior and posterior limbs of the trabeculoseptomarginalis).

Morphologic Left Ventricle

The morphologic left ventricle is an elliptical-shaped structure with a fine trabecular pattern and absent septal attachments of the mitral valve in a normal heart. It consists of an inlet portion containing the mitral valve and a tension apparatus, an apical trabecular zone that is characterized by fine trabeculations, and an outlet zone that supports the aortic valve.

Semilunar Valves

The aortic valve is a trileaflet valve with the left and right cusps giving rise to the left and right coronary arteries, respectively, and the noncoronary cusp lacking a coronary artery connection. Of note, the noncoronary cusp is in fibrous continuity with the anterior leaflet of the mitral valve. The aortic valve has a semilunar attachment to the junction of the ventricular outlet and its great arteries. The aortic cusps have a main core of fibrous tissue with endocardial linings on each surface. The cusps are thickened at the midpoint to form a nodule. The characteristics of the pulmonary valve are similar to

those of its aortic counterpart, but with no coronary ostia arising at the superior portion of the sinuses.

Aortic Arch and Pulmonary Arteries

In a normal heart the aortic arch usually points to the left, with the first branch, the innominate artery, giving rise to the right carotid and subclavian arteries. In general, the left carotid and left subclavian arteries arise separately from the aortic arch. By definition, the ascending aorta is proximal to the origin of the innominate artery, with the transverse aortic arch extending from the innominate artery to the origin of the left subclavian artery. The aortic isthmus is the area between the left subclavian artery and a PDA or ligamentum arteriosum.

Systemic Venous Connections

In a normal heart the left and right innominate veins form the superior caval vein, which connects to the roof of the right atrium. The inferior caval vein connects to the inferior portion of the morphologic right atrium, and the hepatic veins join the inferior caval vein before its insertion into the atrium. The coronary veins drain into the flow of the coronary sinus, with the latter running in the posterior AV groove and terminating in the right atrium. The inferior caval vein is guarded by the eustachian valve and may vary in size.

Pulmonary Venous Drainage in a Normal Heart

The pulmonary veins drain to the left-sided atrium. Usually, three pulmonary veins arise from the trilobed right lung and two pulmonary veins from the bilobed left lung. The pulmonary veins drain into the left atrium in superior and inferior locations. There is a short segment of extraparenchymal pulmonary vein before disappearing into the adjacent hila of the lungs.

Fetal Cardiology

CHD is being diagnosed with increasing frequency during fetal life. Our ability to modify the evolution of structural (by fetal intervention) and physiologic (by drug therapy) heart disease is increasing. Knowledge of the changes in cardiovascular structure, function, and metabolism that occur during fetal development is perhaps more important today than at any time in the past.

The Child and Adolescent. The rapid somatic growth rates in infancy and adolescence are periods of rapid hemodynamic change. Stenotic lesions that may be relatively slowly progressive throughout early childhood need more frequent surveillance during adolescence. Childhood and adolescence are times to begin educating patients, not just their parents, about their heart disease and the responsibilities that go with it. Issues such as the need for compliance with medications, avoidance of smoking and illicit drug use, and pregnancy and contraception counseling are by no means exclusively issues of adults with CHD and increasingly require discussion in the pediatric cardiac clinic.

Indeed, the early teenage years should be regarded as part of the transition process before transfer to adult follow-up. Management of older adolescents plus follow-up of adults with newly discovered or previously treated CHD is a burgeoning new subspecialty that will require careful planning to ensure adequate resources for the increasing number of adult “graduates” of pediatric programs. A coordinated approach with specialists in an affiliated adult CHD clinic is clearly desirable.

The Adult. Patients—and often family members—should understand their cardiac condition in terms of both what has been done thus far and what could happen in the future. This is important for a young patient graduating into the adult world. Patients need information and should become partners in their own care.

Potential long-term complications in adults with CHD (such as arrhythmias, ventricular failure, conduit obstruction, and endocarditis) should be explained to patients who are at relatively high risk for such complications. The possible need for future therapy—medical (antiarrhythmics, anticoagulation, heart failure therapy), catheter based (valve dilation, stents, arrhythmia ablation), or surgical (repeated surgery, transplantation)—should be discussed if the patient may require any such treatment in the short or intermediate future. Day-to-day issues of concern for these young adults need to be addressed, such as exercise prescriptions, driving restrictions, and traveling limitations. Many young people with CHD need advice

regarding career choices, entering the workforce, insurability, and life expectancy.

Many will want to start a family, and therefore reproductive issues will need to be addressed. Discussion of appropriate contraception methods for any given patient should be offered. Counseling before conception about the risk to the mother and the fetus for any given pregnancy should be done by specialized physicians. They will take into account the maternal cardiac anatomy, maternal functional status, maternal life expectancy, risk for transmission of CHD to the offspring, and risk for premature birth. High-risk patients (e.g., Marfan syndrome with aortic root dilation, severe pulmonary hypertension, New York Heart Association [NYHA] class III or IV, and severe aortic stenosis) should be advised against pregnancy. Intermediate-risk patients (e.g., cyanotic, mechanical valve and other warfarin [Coumadin]-requiring patients, moderate left ventricular outflow tract obstruction, moderate to severe left ventricular dysfunction) need to know that pregnancy, although possible, may be complicated and that they will require careful follow-up.

Last but not least, comorbid conditions such as obesity, smoking, high blood pressure, diabetes, and high cholesterol values add new levels of complexity to these adults as they age and must be part of the mandate of the patient’s cardiologist.

PATHOLOGIC CONSEQUENCES OF CONGENITAL CARDIAC LESIONS

Congestive Heart Failure (see Chapters 21 to 29)

Although the basic mechanisms of cardiac failure are similar for all ages, the common causes, time of onset, and frequently the approach to treatment vary with age (see Chapters 24 to 27). Fetal echocardiography now allows the diagnosis of intrauterine cardiac failure. The cardinal findings of *fetal heart failure* are scalp edema, ascites, pericardial effusion, and decreased fetal movements. In *preterm infants*, especially those less than 1500 g in birth weight, persistent patency of the ductus arteriosus is the most common cause of cardiac decompensation, and other forms of structural heart disease are rare. In *full-term newborns* the earliest important causes of heart failure are hypoplastic left heart and aortic coarctation syndromes, sustained tachyarrhythmia, cerebral or hepatic arteriovenous fistula, and myocarditis. Among the lesions commonly producing heart failure *beyond 1 to 2 weeks of age*, when diminished pulmonary vascular resistance allows substantial left-to-right shunting, are VSDs and AV septal defects, TGA, truncus arteriosus, and total anomalous pulmonary venous connection. *Infants younger than 1 year* with cardiac malformations account for 80% to 90% of pediatric patients in whom congestive heart failure develops. In *older children*, heart failure is often due to acquired disease or is a complication of open heart surgical procedures. In the acquired category are rheumatic and endomyocardial diseases, infective endocarditis, hematologic and nutritional disorders, and severe cardiac arrhythmias.

The distinction between left- and right-sided heart failure is less obvious in infants than in older children or adults. Conversely, augmented filling or elevated pressure of the right ventricle in infants reduces left ventricular compliance disproportionately when compared with older children or adults and gives rise to signs of both systemic and pulmonary venous congestion.

Care of infants with heart failure must include careful consideration of the underlying structural or functional disturbance. The general aims of treatment are to achieve an increase in cardiac performance, augment peripheral perfusion, and decrease pulmonary and systemic venous congestion. In many conditions, medical management cannot control the effects of the abnormal loads imposed by a host of congenital cardiac lesions. In these circumstances, interventional catheterization or surgery (see Chapter 28) may be urgently required.

Congestive heart failure is not common in adult CHD practice, although prevention of myocardial dysfunction is a common concern. Heart failure may develop in adult patients with CHD in the presence of a substrate (e.g., myocardial dysfunction, valvular regurgitation)

and a precipitant (e.g., sustained arrhythmia, pregnancy, or hyperthyroidism). Patients prone to the development of congestive failure include those with longstanding volume loads (e.g., valvular regurgitation and left-to-right shunts) and those with primary depression of myocardial function (e.g., systemic right ventricles, ventricles damaged during surgery or because of late treatment of ventricular pressure or volume overload). Treatment depends on a clear understanding of the elements contributing to the decompensation and on addressing each of the treatable components. Standard palliative adult heart failure regimens are frequently used and may include ACE inhibitors, angiotensin receptor blockers, beta blockers, diuretics, resynchronization pacing, transplantation, and other novel therapies. Evidence of the effectiveness of these strategies is relatively lacking, and many of the proven therapies used for heart failure in patients with acquired heart disease have failed to show a demonstrable benefit in treating CHD.⁸

CHD accounts for 40% of pediatric heart transplants but only 2% of adult heart transplants.⁹ Adults receiving heart transplants because of CHD have a mean survival of 11 years, similar to that of patients with other forms of heart disease. Patients who have undergone Fontan surgery tend to have worse outcomes, presumably because they have multiorgan disease.¹⁰ Approximately a third of heart-lung transplants are done for CHD. The 3-year survival rate is approximately 50%, but it is better in patients with Eisenmenger syndrome.

Cyanosis

Definition

Central cyanosis refers to arterial oxygen desaturation resulting from shunting or mixing of systemic venous blood into the arterial circulation. The magnitude of shunting or mixing and the amount of pulmonary blood flow determine the severity of desaturation.

Morphology

Cardiac defects that result in central cyanosis can be divided into two categories: (1) those with increased pulmonary blood flow and (2) those with decreased pulmonary blood flow (**Table 62-4**).

Pathophysiology

Hypoxemia increases renal production of erythropoietin, which in turn stimulates the bone marrow to produce circulating red blood cells, thereby enhancing oxygen-carrying capacity. Secondary erythrocytosis should be present in all cyanotic patients because it is a physiologic response to tissue hypoxia. The improved tissue oxygenation that results from this adaptation may be sufficient to reach a new equilibrium at a higher hematocrit. However, adaptive failure can occur if the increased whole blood viscosity rises so much that oxygen delivery is impaired.¹¹

Clinical Features

Hyperviscosity Syndrome

Although erythrocytosis is now rare because of the diminishing prevalence of untreated cyanotic CHD, it may cause symptoms of hyperviscosity, including headaches, faintness, dizziness, fatigue, altered mentation, visual disturbances, paresthesias, tinnitus, and myalgias. Iron deficiency, a common finding in cyanotic adult patients if

repeated phlebotomies or excessive bleeding occurs, must be treated because it can increase the risk for complications.

Hematologic

Hemostatic abnormalities have been documented in cyanotic patients with erythrocytosis and can occur in up to 20% of patients. The bleeding tendency can be mild and superficial and lead to easy bruising, skin petechiae, and mucosal bleeding, or it can be moderate or life-threatening with hemoptysis or intracranial, gastrointestinal, or postoperative bleeding. An elevated prothrombin and partial thromboplastin time; decreased levels of factors V, VII, VIII, and IX; qualitative and quantitative platelet disorders; increased fibrinolysis; and systemic endothelial dysfunction from increased shear stress have all been implicated.

Central Nervous System

Neurologic complications, including cerebral hemorrhage, can arise secondary to hemostatic defects and can occur in patients taking anticoagulants. Patients with right-to-left shunts may be at risk for paradoxical cerebral emboli, especially if they are iron deficient. A brain abscess should be suspected in a cyanotic patient with a new or different headache or new neurologic symptoms. Air filters should be used in peripheral and central venous lines in cyanotic patients to avoid paradoxical emboli through a right-to-left shunt.

Renal

Renal dysfunction in patients with cyanotic CHD can be manifested as proteinuria, hyperuricemia, or renal failure. Pathologic studies at the level of the glomeruli show evidence of vascular abnormalities, as well as increased cellularity and fibrosis. Hyperuricemia is common and is thought to be due mainly to the decreased reabsorption of uric acid rather than to overproduction associated with erythrocytosis. Urate nephropathy, uric acid nephrolithiasis, and gouty arthritis may occur.

Arthritic

Rheumatologic complications of cyanotic CHD include gout and, especially, hypertrophic osteoarthropathy, which is thought to be responsible for the arthralgias and bone pain affecting up to a third of patients. In patients with right-to-left shunting, megakaryocytes released from bone marrow can bypass the lung. Entrapment of megakaryocytes in the systemic arterioles and capillaries induces the release of platelet-derived growth factor and thus promotes local cell proliferation. New osseous formation with periostitis ensues and gives rise to arthralgia and bone pain.

Coronary Arteries

Patients with central cyanosis display dilated coronaries, and atherosclerotic narrowing is rare. Their level of total cholesterol is also lower than that in the general population.

Interventional Options and Outcomes

Complete Repair

Physiologic or anatomic repair results in total or near-total separation of the pulmonary and systemic circulations in complex cyanotic lesions, which leads to the relief of cyanosis and shunting. Such procedures should be performed whenever feasible. Complete repairs are rarely without long-term sequelae despite the inference in the name, and both physicians and patients should be made aware of the need for regular follow-up in almost all cases.

Palliative Surgical Intervention

Palliative surgical interventions can be performed in patients with cyanotic lesions to increase pulmonary blood flow while allowing the cyanosis to persist. Palliative surgical shunts are summarized in **Table 62-5**. Blalock-Taussig-Thomas, central, and Glenn (also called *cavopulmonary*) shunts are still in use today. Blalock-Taussig-Thomas shunts seldom caused pulmonary hypertension when compared with central shunts and were less prone to causing pulmonary artery distortion. Glenn shunts have the advantage of increasing pulmonary

TABLE 62-4 Cardiac Defects Causing Central Cyanosis

Transposition of the great arteries	Ebstein anomaly
Tetralogy of Fallot	Eisenmenger physiology
Tricuspid atresia	Critical pulmonary stenosis or atresia
Truncus arteriosus	Functionally single ventricle
Total anomalous pulmonary venous return	

Note the five T's and two E's.

**TABLE 62-5 Palliative Systemic-to-Pulmonary Shunts**

Arterial
Blalock-Taussig-Thomas shunt (subclavian artery to PA) Classic—end-to-side, no or reduced ipsilateral arm pulses Current—side-to-side tubular grafts, preserved arm pulses Central shunt (side-to-side tubular graft, aorta to PA) Potts shunt (descending aorta to LPA) Waterston shunt (ascending aorta to RPA)
Venous
Glenn shunt (SVC to ipsilateral PA without cardiac or other PA connection) Bidirectional cavopulmonary (Glenn) shunt (end-to-side SVC-to-LPA and RPA shunt)

LPA = left PA; PA = pulmonary artery; RPA = right PA; SVC = superior vena cava.

flow without imposing a volume load on the systemic ventricle. Glenn shunts require low pulmonary artery pressures to work, and they may be associated with the development over time of pulmonary arteriovenous fistulas, which can worsen the cyanosis.

Transplantation (see Chapter 28)

Transplantation of the heart, transplantation of one or both lungs with surgical cardiac repair, and heart-lung transplantation have been performed in cyanotic patients with or without palliation who were no longer candidates for other forms of intervention. Pulmonary vascular obstructive disease precludes isolated heart transplantation. An increasing number of CHD patients with previous palliation and ventricular failure are successfully undergoing cardiac transplantation.⁹ The timing of transplantation in these patients remains difficult to determine, however.

Other Management of Cyanosis

Phlebotomy

The goal of phlebotomy is control of symptoms. When patients have troubling symptoms of hyperviscosity, are iron replete (normal mean corpuscular volume, hematocrit >65%), and are not dehydrated, removal of 250 to 500 mL of blood over a 30- to 45-minute period should be performed with concomitant quantitative volume replacement. The procedure may be repeated every 24 hours until symptomatic improvement occurs or the hemoglobin level has fallen below 18 to 19 g/dL. Phlebotomy is not indicated for asymptomatic patients.

Iron Replacement

If iron deficiency anemia is found, iron supplements should be prescribed.¹² Cyanotic patients should avoid iron deficiency, which can cause functional deterioration and is associated with an increased risk for stroke and adverse cardiovascular outcome.

Bleeding Diathesis

Platelet transfusions, fresh frozen plasma, vitamin K, cryoprecipitate, and desmopressin can be used to treat severe bleeding. Given the inherent tendency of cyanotic patients to bleed, aspirin, heparin, and warfarin should be avoided unless the risks associated with treatment are outweighed by the risks inherent in nontreatment. Similarly, nonsteroidal anti-inflammatory drugs should be avoided to prevent gastrointestinal bleeding.

Gouty Arthritis

Symptomatic hyperuricemia and gouty arthritis can be treated as needed with colchicine, probenecid, or allopurinol.

Reproductive Issues

Pregnancy in patients with cyanotic CHD (excluding Eisenmenger syndrome) results in a 32% incidence of maternal cardiovascular complications and a 37% incidence of fetal prematurity. Pregnant women with a resting oxygen saturation greater than 85% fare better

than do women with an oxygen saturation lower than 85% (see Chapter 78).

Follow-Up

All cyanotic patients should be managed by a CHD cardiologist, and particular attention should be paid to the underlying heart condition; symptoms of hyperviscosity; systemic complications of cyanosis; change in exercise tolerance; change in saturation levels; and prophylaxis against endocarditis, influenza, and pneumococcal infections. The clinician should remember to measure oxygen saturation only after the patient has been resting for at least 5 minutes and measure blood pressure in the arm contralateral to the side used for an aortopulmonary shunt. In stable cyanotic patients, yearly follow-up is recommended and should include annual flu shots, periodic pneumococcal vaccination, yearly blood work (complete blood count, ferritin, clotting profile, renal function, uric acid), and regular echocardiographic Doppler studies. Home oxygen therapy may have a role in increasing oxygen saturation, but the clinical indications and outcomes are not clear.

Pulmonary Hypertension

Pulmonary hypertension is a common accompaniment of many congenital cardiac lesions,¹³ and the status of the pulmonary vascular bed is often the principal determinant of the clinical manifestations, the course, and whether corrective treatment is feasible (see Chapter 74). Recent consensus statements provide important information on this general topic.^{14,15} Increases in pulmonary arterial pressure result from elevations in pulmonary blood flow and/or resistance, the latter sometimes being caused by an increase in vascular tone but usually being the result of underdevelopment and/or obstructive or obliterative structural changes within the pulmonary vascular bed. Although pulmonary hypertension usually affects the entire pulmonary vascular bed, it may occur focally. For example, unilateral pulmonary hypertension may occur in an overshunted lung (the other lung perhaps being protected and fed by a cavopulmonary Glenn shunt) or in lung segments supplied by aortopulmonary collateral flow.

Pulmonary vascular resistance normally falls rapidly immediately after birth because of the onset of ventilation and ensuing pulmonary vasodilation. Subsequently, the medial smooth muscle of pulmonary arterial resistance vessels thins gradually. This latter process is often delayed by several months in infants with large aortopulmonary or ventricular communications, at which time levels of pulmonary vascular resistance are still somewhat elevated. In patients with high pulmonary arterial pressure from birth, failure of normal growth of the pulmonary circulation may occur, and anatomic changes in the pulmonary vessels in the form of proliferation of intimal cells and intimal and medial thickening often progress such that vascular resistance in an older child or adult may ultimately become relatively fixed by obliterative changes in the pulmonary vascular bed. The causes of pulmonary vascular obstructive disease remain unknown, although increased pulmonary arterial blood pressure, elevated pulmonary venous pressure, erythrocytosis, systemic hypoxia, acidemia, and the nature of the bronchial circulation have all been implicated. Quite likely, injury to pulmonary vascular endothelial cells initiates a cascade of events that involve the release or activation of factors that alter the extracellular matrix, induce hypertrophy, cause proliferation of vascular smooth muscle cells, and promote connective tissue protein synthesis. Considered together, these factors may permanently alter vessel structure and function.

Mechanisms of Development. Intimal damage appears to be related to shear stress because endothelial cell damage occurs at high shear rates. A reduction in pulmonary arteriolar lumen size because of either thickened medial muscle or vasoconstriction increases the velocity of flow. Shear stress also increases as blood viscosity rises; therefore infants with hypoxemia and high hematocrit levels, as well as increased pulmonary blood flow, are at increased risk for the development of pulmonary vascular disease. In patients with left-to-right shunts, pulmonary arterial hypertension, if not present in infancy or childhood, may never occur or may not develop until the third or

fourth decade or later. Once developed, the intimal proliferative changes with hyalinization and fibrosis are not reversible by repair of the underlying cardiac defect. In patients with severe pulmonary vascular obstructive disease, arteriovenous malformations may develop and predispose to massive hemoptysis.

Most vexing is the variability among patients with the same or similar cardiac lesions in both time of appearance and rate of progression of the pulmonary vascular obstructive process. Although genetic influences may be operative (an example is the apparent acceleration of pulmonary vascular disease in patients with CHD and trisomy 21), evidence is now accumulating for important genetic, prenatal, and postnatal modifiers of the pulmonary vascular bed that appear, at least in part, to be dependent on the lesion. Thus a quantitative variability exists in the pulmonary vascular bed related to the number, not just the size and wall structure, of arterial vessels within the pulmonary circulation, all of which may be modified by coexisting CHD.

Eisenmenger Syndrome Definition

Eisenmenger syndrome, a term coined by Paul Wood, is defined as pulmonary vascular obstructive disease that develops as a consequence of a large preexisting left-to-right shunt such that pulmonary artery pressures approach systemic levels and the direction of flow becomes bidirectional or right to left. Congenital heart defects that can result in Eisenmenger syndrome include “simple” defects such as ASD, VSD, and PDA, as well as more “complex” defects such as AV septal defect, truncus arteriosus, aortopulmonary window, and univentricular heart. The high pulmonary vascular resistance is generally established in early childhood (often by 4 years of age, except in those with ASD) and is sometimes present from birth.

Natural History of Unoperated Patients

Patients with defects that allow free communication between the pulmonary and systemic circuits at the aortic or ventricular levels usually have a fairly healthy childhood and gradually become overtly cyanotic during their second or third decade. Exercise intolerance (dyspnea and fatigue) is proportional to the degree of hypoxemia or cyanosis. In the absence of complications these patients generally have excellent to good functional capacity up to their third decade and thereafter typically experience a slowly progressive decline in their physical abilities. Most patients survive to adulthood, with reported 77% and 42% survival rates at 15 and 25 years of age, respectively.

Congestive heart failure in patients with Eisenmenger syndrome usually occurs after 40 years of age. The most common modes of death are sudden death (30%), congestive heart failure (25%), and pulmonary hemorrhage (15%). Pregnancy, perioperative mortality at the time of noncardiac surgery, and infectious causes (brain abscesses and endocarditis) account for most of the remainder.

Clinical Manifestations

Patients can have the following complications: those related to their cyanotic state; palpitations in nearly half the patients (atrial fibrillation/flutter in 35%, ventricular tachycardia in up to 10%); hemoptysis in approximately 20%; pulmonary thromboembolism, angina, syncope, and endocarditis in approximately 10% each; and congestive heart failure. Hemoptysis is usually due to bleeding bronchial vessels or pulmonary infarction. Physical examination reveals central cyanosis and clubbing of the nail beds. Patients with Eisenmenger PDA can have pink nail beds on the right (more than on the left) hand and cyanosis and clubbing of both feet, so-called differential cyanosis. This occurs because venous blood shunts through the ductus and enters the aorta distal to the subclavian arteries. Jugular venous pressure in patients with Eisenmenger syndrome can be normal or elevated, especially with prominent *v* waves when tricuspid regurgitation is present. Signs of pulmonary hypertension—right ventricular heave, palpable and loud P_2 , and a right-sided S_4 —are typically present. In many patients a pulmonary ejection click and a soft and scratchy systolic ejection murmur, attributable to dilation of the pulmonary trunk, and a high-pitched decrescendo diastolic

murmur of pulmonary regurgitation (Graham Steell murmur) are audible. Peripheral edema is absent until right-sided heart failure ensues.

Laboratory Investigations

Electrocardiography. Peaked P waves consistent with right atrial overload and evidence of right ventricular hypertrophy with right-axis deviation are the rule. Atrial arrhythmias can be present.

Chest Radiography. Dilated central pulmonary arteries with rapid tapering of the peripheral pulmonary vasculature are the radiographic hallmarks of Eisenmenger syndrome. Pulmonary artery calcification may be seen and is diagnostic of longstanding pulmonary hypertension. Eisenmenger syndrome secondary to VSD or PDA usually has a normal or only slightly increased cardiothoracic ratio. Eisenmenger syndrome secondary to an ASD typically has a large cardiothoracic ratio because of right atrial and ventricular dilation, along with an inconspicuous aorta reflecting low life-long cardiac output. Calcification of the duct may be seen in Eisenmenger PDA.

Echocardiography. The intracardiac defect should be seen readily along with bidirectional shunting. A pulmonary hypertensive PDA is not seen easily. Evidence of pulmonary hypertension is found. Assessment of right ventricular function adds prognostic value.

Cardiac Catheterization. Cardiac catheterization not only provides direct measurement of pulmonary artery pressure and can thereby document the existence of severe pulmonary hypertension but can also allow assessment of reactivity of the pulmonary vasculature. Administration of pulmonary arterial vasodilators (O_2 , nitric oxide, prostaglandin I_2 [epoprostenol]) can discriminate among patients in whom surgical repair is contraindicated and those with reversible pulmonary hypertension who may benefit from surgical repair. Radiographic contrast material may cause hypotension and worsening cyanosis and should be used cautiously.

Open-Lung Biopsy. Open-lung biopsy should be considered only when reversibility of the pulmonary hypertension is uncertain from the hemodynamic data. An expert opinion will be necessary to determine the severity of the changes, often using the Heath-Edwards classification.

Indications for Intervention

The underlying principle of clinical management in patients with Eisenmenger syndrome is to avoid any factors that may destabilize the delicately balanced physiology. In general, an approach of nonintervention has traditionally been recommended, although research on the treatment of pulmonary hypertension has provided evidence of benefit with advanced therapy.¹⁶ The main interventions are therefore directed toward preventing complications (e.g., flu shots and pneumococcal vaccine to reduce the morbidity of respiratory infections) or restoring physiologic balance (e.g., iron replacement for iron deficiency, antiarrhythmic management of atrial arrhythmias, and diuretics for right-sided heart failure). As a general rule, the first episode of hemoptysis should be considered an indication for investigation. Bed rest is usually recommended, and although generally self-limited, each such episode should be regarded as potentially life-threatening, and a treatable cause should be sought. When patients are severely incapacitated from severe hypoxemia or congestive heart failure, the main intervention available is lung transplantation (plus repair of the cardiac defect) or, with somewhat better results, heart-lung transplantation. This is generally reserved for individuals without contraindications who are thought to have a 1-year survival rate of less than 50%. Such assessment is fraught with difficulty because of the unpredictability of the time course of the disease and the risk for sudden death.

Noncardiac surgery should be performed only when absolutely necessary because of its high associated mortality. Patients with Eisenmenger syndrome are particularly vulnerable to the alterations in hemodynamics induced by anesthesia or surgery, such as a minor decrease in systemic vascular resistance, which can increase right-to-left shunting and possibly potentiate cardiovascular collapse. Local anesthesia should be used whenever possible. Avoidance of prolonged fasting and especially dehydration, the use of antibiotic prophylaxis when appropriate, and careful intraoperative monitoring are recommended. The choice of general versus epidural/spinal anesthesia is controversial. An experienced cardiac anesthetist with

an understanding of Eisenmenger syndrome physiology should administer anesthesia. Additional risks associated with surgery include excessive bleeding, postoperative arrhythmias, and deep venous thrombosis with paradoxical emboli. An “air filter” or “bubble trap” should be used for most intravenous lines in cyanotic patients. Early ambulation is recommended. Postoperative care in an intensive care unit setting is optimal.

Interventional Options and Outcomes

Oxygen

Supplemental nocturnal oxygen has been shown to have no impact on exercise capacity or on survival in adult patients with Eisenmenger syndrome. Supplemental oxygen during commercial air travel is often recommended, but a scientific basis for this recommendation is lacking.

Transplantation

Lung transplantation may be undertaken in association with repair of existing cardiovascular defects. Alternatively, heart-lung transplantation may be required if the intracardiac anatomy is not correctable. The 3-year survival rate after heart-lung transplantation for CHD is 50%.¹⁷ The subgroup of patients with Eisenmenger syndrome may do better, with a 50% 5-year survival rate. These procedures offer the best hope to individuals with end-stage CHD who are confronting death and have an intolerable quality of life.

Medical Therapy

ENDOTHELIN RECEPTOR ANTAGONISTS. A randomized trial of a nonselective endothelin receptor antagonist (bosentan) in patients with Eisenmenger syndrome showed that pulse oximetry was not altered. When compared with placebo, bosentan reduced the pulmonary vascular resistance index and pulmonary artery pressure and improved 6-minute walk distance and functional class. A smaller observational study of bosentan, 125 mg twice per day, in nine patients with Eisenmenger syndrome showed an improvement in functional class and increased resting oxygen saturation levels. In another study, bosentan was less effective in patients with Down syndrome.¹⁸

PHOSPHODIESTERASE INHIBITORS. Sildenafil (Viagra) in a large double-blind, placebo-controlled study administered in various doses to 278 patients with symptomatic pulmonary arterial hypertension of different causes improved 6-minute walk distance, an improvement maintained for the 1 year of the trial; increased functional class; and modestly improved pulmonary arterial pressure and cardiac output. A second randomized, placebo-controlled, double-blind crossover study of a smaller group of patients produced similar improvements. Additional experience has recently been reported,^{19,20} and the importance of considering safety issues in treating these patients has been highlighted.²¹

Follow-Up

Patient education is critical. Avoidance of over-the-counter medications, dehydration, smoking, high-altitude exposure, and excessive physical activity should be stressed. Avoidance of pregnancy with appropriate contraceptive methods is of paramount importance. Annual flu shots, a single dose of pneumococcal vaccine, and the use of endocarditis prophylaxis together with proper skin hygiene (avoidance of nail biting) are recommended. Yearly assessment of the complete blood cell count and uric acid, creatinine, and ferritin levels should be done to monitor treatable causes of deterioration.

Cardiac Arrhythmias (see Chapters 34 to 39)

Most arrhythmias (see Chapter 37) encountered in teenagers and young adults develop in association with previously operated CHD. Arrhythmias can be a major clinical challenge in adolescent and adult patients with CHD. They are the most frequent reason for emergency department visits and hospital admissions, and they are usually recurrent and may worsen or become less responsive to treatment over time. Treatment may be challenging.

Atrial Arrhythmias

Atrial flutter and, to a lesser degree, atrial fibrillation are most common (see Chapter 38). Atrial flutter tends to reflect right atrial abnormalities, whereas atrial fibrillation tends to reflect left atrial abnormalities. Atrial flutter in such patients is often atypical in appearance and behavior and is better called *intra-atrial reentrant tachycardia*. Recognition of atrial flutter can be difficult, and the observer must be vigilant in recognizing 2:1 conduction masquerading as sinus rhythm. Recurrence is likely and should not necessarily be assumed to represent failure of the management strategy. Conditions in which atrial flutter is most likely are Mustard/Senning repairs of TGA, repaired or unrepaired ASDs, repaired tetralogy of Fallot, Ebstein anomaly of the tricuspid valve, and after a Fontan operation. Atrial flutter may reflect hemodynamic deterioration in patients who have undergone Mustard, Senning, tetralogy of Fallot, or Fontan repairs. Its onset is usually associated with more symptoms and functional limitation.

The pharmaceutical agents most commonly used for therapy are warfarin, beta blockers, amiodarone, sotalol, propafenone, and digoxin. As a rule, patients with good ventricular function can receive sotalol or propafenone, whereas those with depressed ventricular function should receive amiodarone. Other therapies, including pacemakers, ablative procedures, and innovative surgery, are being both applied and refined. Sustained ventricular tachycardia or ventricular fibrillation occurs less often, generally in the setting of ventricular dilation, dysfunction, and scarring. Although sudden death is common in several conditions, the mechanism is poorly understood.

Ventricular Tachycardia

This arrhythmia can occur as a manifestation of the proarrhythmic effects of various agents, in patients with acute myocardial injury or infarction, and in CHD patients with severe ventricular dysfunction. In particular, sustained ventricular tachycardia has developed in patients with repaired tetralogy of Fallot, in whom it is seen as a manifestation of hemodynamic problems requiring repair, as a reflection of right ventricular dilation and dysfunction, and in relation to ventricular scarring.

Sudden Death (See Chapter 39)

In contrast to adults, children seldom die suddenly and unexpectedly of cardiovascular disease. Nonetheless, sudden death at any age has been reported with arrhythmias, aortic stenosis, hypertrophic obstructive cardiomyopathy, idiopathic pulmonary arterial hypertension, Eisenmenger syndrome, myocarditis, congenital complete heart block, primary endocardial fibroelastosis, and certain anomalies of the coronary arteries.

Atrioventricular Block

First-degree AV block is commonly seen in patients with AV septal defects, Ebstein anomaly, and complete TGA (D-TGA) and in older patients with ASD. Complete heart block may develop in patients with cc-TGA and may occur postoperatively in these and other patients. When pacing is required, epicardial leads are usually placed in cyanotic patients because of their risk for paradoxical embolism. Many adult patients with CHD are prone to problems of vascular access as a result of previous surgeries and pacing leads.

Infective Endocarditis (see Chapter 64)

Infective endocarditis complicating CHD is uncommon before 2 years of age, except in the immediate postoperative period. Recent guidelines for endocarditis prophylaxis have substantially altered clinical practice.^{22,23} Maintenance of excellent oral hygiene is encouraged most strongly. Antibiotic prophylaxis before dental procedures is recommended for patients with prosthetic heart valves; when prosthetic material is used for cardiac valve repair; in those with a previous history of infective endocarditis, persistently cyanotic CHD, or residual defects adjacent to a prosthetic patch or prosthetic device; for the first 6 months after placement of prosthetic material or a device for

CHD; and in cardiac transplant recipients in whom cardiac valvulopathy develops.

Chest Pain (See Chapter 50)

Angina pectoris is an uncommon symptom of CHD, although in patients with typical pain, full surveillance for coronary abnormalities (e.g., abnormal origin and course, ostial stenosis, myocardial bridging) is required. The pain caused by pericarditis is commonly of acute onset and associated with fever and can be identified by specific physical, radiographic, and echocardiographic findings. Most commonly, late postoperative chest pain is musculoskeletal in origin and may be reproduced with upper extremity movement or by palpation.

Syndromes in Congenital Heart Disease

ALCAPA Syndrome. The acronym ALCAPA stands for anomalous left coronary artery arising from the pulmonary artery. It is also called *Bland-White-Garland syndrome*. (See Videos 62-1 through 62-3.)

Alagille Syndrome. This autosomal dominant syndrome consists of intrahepatic cholestasis, characteristic facies, butterfly-like vertebral anomalies, and varying degrees of peripheral pulmonary artery stenosis or diffuse hypoplasia of the pulmonary artery and its branches. It is most commonly caused by point mutations in the *JAG1* gene on chromosome 20p and is less frequently caused by deletions of chromosome 20p (7% of cases) or point mutations in *NOTCH2* (1% of cases).

22q11 Deletion Syndrome. This syndrome is caused by a microdeletion in chromosome 22q11, which results in a wide clinical spectrum and is also known as DiGeorge or velocardiofacial or Takao syndrome. Cardiac defects include conotruncal defects such as an interrupted aortic arch, tetralogy of Fallot, truncus arteriosus, and double-outlet right ventricle.

CHARGE Syndrome. CHARGE is an acronym for ocular coloboma, congenital heart defects, choanal atresia, retardation of growth and development, genital hypoplasia, and ear anomalies associated with deafness. The phenotype is highly variable. Congenital heart defects seen in the CHARGE association are tetralogy of Fallot with or without other cardiac defects, AV septal defect, double-outlet right ventricle, double-inlet left ventricle, TGA, interrupted aortic arch, and others. Most cases are caused by mutations or deletions of a gene encoding a chromatin remodeling protein, *CHD7*.

Down Syndrome. This is the most common genetic malformation and is caused by trisomy 21. Most patients (95%) have complete trisomy of chromosome 21; some have translocation or mosaic forms. The phenotype is diagnostic (short stature, characteristic facial appearance, mental retardation, brachydactyly, atlantoaxial instability, and thyroid and white blood cell disorders). Congenital heart defects are frequent (40%), with AV septal defect, VSD, and PDA being the most common. Patients with Down syndrome are prone to earlier and more severe pulmonary vascular disease than otherwise expected as a result of the lesions identified. Health supervision guidelines for patients with Down syndrome provide management and screening recommendations.²⁴

Ellis-van Creveld Syndrome. This is an autosomal recessive skeletal dysplasia syndrome in which common atrium, primum ASD, and partial AV septal defects are the most common cardiac lesions. This syndrome is one of a growing class of “ciliopathies” and is caused by mutations in *EVC1* or *EVC2*.

Holt-Oram Syndrome. This autosomal dominant syndrome consists of radial abnormalities of the forearm and hand in association with secundum ASD (most common), VSD, or rarely, other cardiac malformations. It is caused by mutations in *TBX5* and is characterized by phenotypic variability within and between families.

LEOPARD Syndrome. This autosomal dominant condition is a close cousin of Noonan syndrome and shares a similar genetic substrate (deletion of the *PTPN11* gene). It includes lentigines, electrocardiographic abnormalities, ocular hypertelorism, pulmonary stenosis, abnormal genitalia, retardation of growth, and deafness. Rarely, cardiomyopathy or complex CHD may be present.

Noonan Syndrome. This autosomal dominant syndrome is phenotypically somewhat similar to Turner syndrome but has a normal chromosomal complement. Noonan syndrome is caused by mutations in the *PTPN11* gene, as well as the *KRAS*, *SOS1*, *NRAS*, and *RAF1* genes, which has led to the idea that genes of the renin-angiotensin-system pathway contribute to Noonan and related syndromes. Noonan

syndrome is associated with congenital cardiac anomalies, especially dysplastic pulmonary valve stenosis, pulmonary artery stenosis, and ASD. Hypertrophic cardiomyopathy is less common. Congenital lymphedema is a commonly associated anomaly.

Rubella Syndrome. This previously serious condition has largely been eradicated in regions with vaccination programs. It consists of a wide spectrum of malformations caused by rubella infection early in pregnancy, including cataracts, retinopathy, deafness, CHD, bone lesions, and mental retardation. The spectrum of congenital heart lesions is wide and includes pulmonary artery stenosis, PDA, tetralogy of Fallot, and VSD.

Scimitar Syndrome (Videos 62-4 and 62-5). This is a constellation of anomalies that includes total or partial anomalous pulmonary venous connection (PAPVC) of the right lung to the inferior vena cava and is often associated with hypoplasia of the right lung and right pulmonary artery. The lower portion of the right lung (sequestered lobe) tends to receive additional arterial supply from the abdominal aorta. The name of the syndrome is derived from the appearance on a posteroanterior chest radiograph of the shadow formed by the anomalous pulmonary venous connection, which resembles a Turkish sword, or scimitar.

Shone Complex (Syndrome). This is an association of multiple levels of left ventricular inflow and outflow obstruction (subvalvular and valvular left ventricular outflow tract obstruction, coarctation of the aorta, and mitral stenosis [parachute mitral valve and supramitral ring]) (Video 62-6). The genetic basis of left-sided lesions, including mitral stenosis, aortic stenosis, left ventricular hypoplasia, and coarctation, is shared, but for the most part causal genes have not been found. *NOTCH1* mutations are associated with aortic stenosis.

Turner Syndrome. This clinical syndrome is due to the 45 XO karyotype in approximately 50% of cases, with various other X chromosome abnormalities accounting for the remainder. There is a characteristic but variable phenotype and an association with congenital cardiac anomalies, especially postductal coarctation of the aorta and other left-sided obstructive lesions, as well as PAPVC without ASD. The female phenotype varies with the age at initial evaluation and is somewhat similar to that of Noonan syndrome.

Williams Syndrome. This contiguous gene syndrome is associated with inherited or sporadic deletions in chromosome 7q11.23. The cardiovascular features are caused by the loss of function of *ELASTIN*, one of the approximately 30 genes in the deletion. Williams syndrome is associated with intellectual deficit, infantile hypercalcemia, a characteristic phenotype, and CHD, especially supravalvular aortic stenosis and multiple peripheral pulmonary stenoses. Isolated familial supravalvular aortic stenosis is seen in otherwise phenotypically and intellectually normal families who carry *ELASTIN* mutations, but not the full deletion.

EVALUATION OF PATIENTS WITH CONGENITAL HEART DISEASE

Physical Examination

Although advances in technology have profoundly improved our diagnostic ability, there is still a role for detailed clinical examination in the assessment and follow-up of patients with unoperated, palliated, and repaired CHD. The relevant findings pertaining to specific abnormalities are outlined in the appropriate sections that follow, but some general principles bear consideration (see Chapter 11).

Physical Assessment

The presence of characteristic facial or somatic features of an underlying syndrome may be a strong clue to the type of heart disease (e.g., Williams, Noonan, Down) at any age. Central cyanosis can be difficult to diagnose clinically when mild but should be actively excluded by oximetry in any patient with suspected CHD. One should assess both cardiac and visceral situs and not assume that the heart will be left-sided. Careful surveillance of the chest wall for scars is also important in adolescents and adults, who do not always know or report the type and sequence of their surgical interventions.

Examination of the upper and lower limb peripheral pulses is important. Delay, absence, or reduction of a pulse is an important clue to the presence of arterial obstruction and its site. The left brachial pulse is often compromised by surgery for coarctation, and

**VIDEO 62-1**

Anomalous origin of the left coronary artery from the pulmonary artery. This loop taken in the long-axis view shows reduced left ventricular function and echogenic papillary muscles.

VIDEO 62-2

Anomalous origin of the left coronary artery from the pulmonary artery. This short-axis loop shows an anomalous left coronary artery entering the main pulmonary artery in close proximity to the left aortic sinus. Note the retrograde flow in the left coronary system.

VIDEO 62-3

A young woman with a history of a primum ASD and cleft mitral valve was evaluated for angina and ischemia of the entire left coronary distribution. Angiography revealed an anomalous left coronary artery originating from the right pulmonary artery. Echocardiographic images demonstrated abnormal color flow in the septum, moderate mitral regurgitation, and a large right coronary artery origin. The patient was treated by placing a Amplatzer Vascular Plug (St. Jude Medical, Inc., St. Paul, Minn) in the left main coronary artery to transform the left coronary artery from a venous conduit into a pressurized arterial circulation. After implantation of the device, note the slowing of flow in the left coronary artery and filling of the coronary sinus. The ischemia had resolved completely on subsequent functional testing.

VIDEO 62-4

Scimitar syndrome. This long-axis loop of the inferior vena cava shows right-sided pulmonary veins draining into it in close proximity to the right atrium.

VIDEO 62-5

Scimitar syndrome. This suprasternal coronal loop shows the branch pulmonary arteries and the left-sided pulmonary veins draining into the left atrium. The right-sided pulmonary veins are not identified as they drain into the inferior vena cava.

VIDEO 62-6

Parachute mitral valve. This short-axis loop shows a single papillary muscle supporting the mitral valve.

blood pressure should not be measured in only the left arm. Similarly, other palliative procedures (Blalock-Taussig-Thomas shunt, interposition grafts) may affect either or both upper limb pulses. Assessing the femoral and carotid pulses in addition to the upper limb pulses is important in such patients. Just as in acquired disease, pulse volume and character also provide important information regarding the severity of obstructive or regurgitant left-sided heart disease. A low-volume pulse (usually with a narrow pulse pressure) reflects low cardiac output. Pulsus alternans signifies severe systemic ventricular dysfunction. Pulsus paradoxus points to cardiac tamponade. In adolescents and adults, jugular venous pressure examination is often important. It may provide an indication of cardiac decompensation, cardiac chamber hypertrophy or restriction, valvular regurgitation or stenosis, arrhythmia or conduction disturbance, cardiac tamponade, pericardial constriction, and other phenomena.

Auscultation

The rules of auscultation also follow those developed for acquired heart disease. However, cardiac and vascular malposition may significantly affect the appreciation of heart sounds and murmurs. For example, in TGA treated by an atrial switch procedure, the aorta remains anterior to the pulmonary artery. Consequently the aortic component of the second sound can be exceptionally loud, and the pulmonary component may be virtually inaudible, thus making it difficult to estimate pulmonary arterial pressure clinically under such circumstances. Conversely, when a valved conduit is present between the right ventricle and pulmonary artery, the pulmonary closure sound may be extremely loud even though pulmonary artery diastolic pressure is low. This is because the conduit is frequently adherent to the chest wall and assists in transmission of sound to a stethoscope placed close to it. Calcification of the semilunar valves is relatively unusual in childhood and early adult life, which makes differentiation of valve stenosis from subvalve or supravalue narrowing by the presence of an ejection click more precise in these patients. Differentiation of multiple murmurs is sometimes a challenge. Systolic and/or diastolic murmurs in an individual may have several causes, and supplementary clinical information may be required to establish their significance in some cases. Auscultation over the entire anterior and posterior aspects of the chest wall is important. The continuous murmurs of aorto-aortic collateral arteries in coarctation may be audible only between the shoulder blades posteriorly, for example, and similarly, the presence of a localized distal pulmonary artery stenosis or the presence of an aortopulmonary collateral artery may be detected only in a localized area of the chest wall.

The Electrocardiogram

The electrocardiogram (ECG) (see Chapter 12) remains an important tool in the assessment of CHD. Heart rhythm and rate, as well as AV conduction, can be evaluated. The dominant theme that runs through ECGs in patients with CHD is the prevalence of right-sided heart disease. It often takes the form of right-axis deviation along with right atrial and right ventricular hypertrophy. Right ventricular hypertrophy may reflect pulmonary hypertension, right ventricular outflow tract obstruction, or a subaortic right ventricle. An incomplete right bundle branch block often indicates right ventricular hypertrophy secondary to pressure (e.g., pulmonary hypertension or pulmonary stenosis) or volume (e.g., ASD) overload. Right ventricular volume overload is likely when the r' in V_1 is less than 7 mm. Very wide QRS complexes should be seen as possible manifestations of dilated and dysfunctional ventricles, most specifically in patients with a combination of repaired tetralogy of Fallot, complete right bundle branch block, and severe pulmonary regurgitation. The ECG may be uninterpretable in patients with abnormal cardiac or visceral situs unless it is clear where the leads were placed.

Atrial flutter (often in an atypical form—so-called *intra-atrial reentrant tachycardia*) is much more common than atrial fibrillation in young patients. First-degree block is frequently seen in patients with AV septal defects, cc-TGA, and Ebstein anomaly. Complete heart

block most often occurs in patients with cc-TGA, as well as in those with earlier-era VSD repairs.

Left atrial overload may reflect increased pulmonary blood flow, as well as AV valve dysfunction and myocardial failure. Left-axis deviation should make one think of an AV septal defect, a univentricular heart, and a hypoplastic right ventricle. Deep q waves in the left chest leads can be caused by left ventricular volume overload in a young person with aortic or mitral regurgitation. Pathologic Q waves can be evidence of the anomalous origin of the left coronary from the pulmonary artery.

The Chest Radiograph

The chest radiograph (see Chapter 15) is another valuable tool for the discerning physician caring for patients with congenital heart defects. Although more recent technologies have rightly attracted much attention, there is value in learning how to interpret the chest radiograph. Some teaching points can be made that may anchor interpretation of the chest radiographs of some CHD patients. The following sections provide a number of clinical and radiographic differential diagnoses.

Criteria for Shunt Vascularity. The criteria include (1) uniformly distributed vascular markings with absence of the normal lower lobe vascular predominance, (2) right descending pulmonary artery diameter that exceeds 17 mm, and (3) a pulmonary artery branch that is larger than its accompanying bronchus (best noted in the right parahilar area). Prominent vascularity is apparent only if the pulmonary-to-systemic flow ratio is greater than 1.5:1. As a rule, overt cardiac enlargement usually implies a shunt greater than 2.5:1. Anemia, pregnancy, thyrotoxicosis, and a pulmonary AV fistula may mimic shunt vascularity.

Cyanotic Patients with Shunt Vascularity. This group includes a single ventricle with transposition, persistent truncus arteriosus, tricuspid atresia without significant pulmonary outflow obstruction, total anomalous pulmonary venous connection, double-outlet right ventricle, and a common atrium.

Cyanotic Patients with a Ventricular Septal Defect and Normal or Decreased Pulmonary Vascularity. This group includes tetralogy of Fallot, tricuspid atresia with pulmonary stenosis, single ventricle and pulmonary stenosis, D-TGA with pulmonary stenosis, cc-TGA with pulmonary stenosis, double-outlet right ventricle with pulmonary stenosis, pulmonary atresia, and asplenia syndrome.

Causes of Retrosternal Filling on the Lateral Chest Radiograph. Causes include right ventricular dilation, TGA, ascending aortic aneurysm, and noncardiovascular masses (e.g., lymphoma, thymoma, teratoma, and thyroid).

Causes of a Straight Left-Sided Heart Border. Such causes include right ventricular dilation, left atrial dilation, cc-TGA, pericardial effusion, Ebstein anomaly, and congenital absence of the left pericardium.

Cardiovascular Diseases Associated with Scoliosis. Such diseases include cyanotic CHD, Eisenmenger syndrome, Marfan syndrome, and occasionally mitral prolapse.

Causes of Large Central Pulmonary Arteries. Causes include increased pulmonary flow (main pulmonary artery and branches), increased pulmonary pressure (main pulmonary artery and branches), valvular pulmonary stenosis (main and left pulmonary arteries), and idiopathic dilation of the pulmonary artery (main pulmonary artery).

Situs Solitus with Cardiac Dextroversion. Situs solitus with cardiac dextroversion is associated with CHD in more than 90% of cases. Up to 80% have a congenitally corrected transposition with a high incidence of associated VSD, pulmonary stenosis, and tricuspid atresia. *Situs inversus with dextrocardia* carries a low incidence of CHD, whereas *situs inversus with levocardia* is virtually always associated with severe CHD.

Cardiovascular Magnetic Resonance Imaging

Cardiac MRI (see Chapter 17) in adolescents and adults with CHD has become of ever-increasing importance in the past decade. MRI can circumvent the echocardiographic problem of suboptimal

visualization of the heart in adult patients, especially those who have undergone surgery. This technique can now generate information never previously available and do so more easily or more accurately than by other means. New MRI image acquisition methods are faster and provide improved temporal and spatial resolution. Major advances in hardware design, new pulse sequences, and faster image reconstruction techniques now permit rapid high-resolution imaging of complex cardiovascular anatomy. MRI can produce quantitative measures of ventricular volume, mass, and ejection fraction. MRI can quantify blood flow in any vessel.

Cardiac MRI is of particular value when transthoracic echocardiography cannot provide the needed diagnostic information; as an alternative to diagnostic cardiac catheterization; and for MRI's unique capabilities, such as tissue imaging, myocardial tagging, and vessel-specific flow quantification. The value of MRI over echocardiography for evaluation of the right ventricle is increasingly becoming appreciated. The capability of MRI to assess the right ventricle is of great importance because the right ventricle is a key component of many of the more complex CHD lesions. In addition, MRI can be used to evaluate valve regurgitation, postoperative systemic and pulmonary venous pathways, Fontan pathways, and the great vessels. MRI should be considered the main imaging modality in adolescents and adults with repaired tetralogy of Fallot, TGA, Fontan procedure, and diseases of the aorta. Late gadolinium enhancement frequently demonstrates myocardial scarring in both operated and unoperated CHD and is increasingly reported to be related to functional and arrhythmic outcomes. In the near future we will see real-time MRI to allow MRI-guided interventional procedures and molecular imaging, which will further expand the capabilities of MRI.

Echocardiography (See Chapter 14)

Fetal Echocardiography

General Considerations

Fetal echocardiography has graduated from being a special area of interest for some pediatric cardiologists to one of standard care. It should be offered to all mothers with increased risk for a fetal cardiac anomaly, including those with or who have a partner with CHD and those with a strong family history. As early as 16 weeks' gestation, excellent images of the fetal cardiac structures can be obtained by the transabdominal route, along with an appreciation of cardiac and placental physiology through the use of Doppler technology. Transvaginal ultrasound is a newer approach that permits the echocardiographer to obtain images at approximately 13 to 14 weeks' gestation. Data are beginning to emerge on the benefit of this approach, although current opinion would support follow-up cardiac screening at 18 weeks' gestation. Even though it has some application in patients at higher risk for recurrent CHD (e.g., obstructive left-sided lesions), its accuracy has yet to be determined, in part because of the limited number of views that are possible as a result of the relatively fixed position of the transducer.

Impact of Fetal Echocardiography

Most major structural congenital heart defects are now accurately categorized with fetal echocardiography. Once the abnormalities are identified, families and obstetric caregivers can be counseled about the impact of the abnormality on both the fetus and family. Decisions appropriate to the family and fetus can then be made. Although termination of pregnancy is one of the consequences of prenatal diagnosis, it is not the main objective. In fact, data are starting to appear in the literature indicating that prenatal diagnosis of some major cardiac malformations has a direct impact on outcome, including survival, morbidity, and cost. This is in part due to the fact that when a prenatal diagnosis is made, subsequent caregivers are prepared for the immediate postnatal effects of the defect. For example, in those with hypoplastic left heart syndrome and other duct-dependent lesions, prostaglandin E_1 can be started immediately after birth, optimally in a hospital within or attached to a pediatric cardiology facility.

Fetal echocardiography has also permitted improved understanding of the evolution of certain congenital cardiac malformations. For example, although the fetal heart is fully formed by the time that a prenatal scan is performed, tremendous growth of the cardiac structures must still occur. Therefore in some circumstances a cardiac chamber that may appear only mildly hypoplastic at 16 weeks' gestation may be profoundly affected at the time of birth. This has a major impact on management of the newborn, as well as on the counseling process at 16 weeks' gestation.

Direct Fetal Intervention

The next step is direct intervention for specific cardiac lesions. This has initially involved obstructive lesions, thus far being limited mainly to the left ventricle. The rationale behind this therapy is based on the notion that relief of obstructive outflow tract lesions will permit growth of the affected ventricle and potentially change a neonatal pathway from univentricular to biventricular. Cardiac surgery on the fetus is also a future option, and indeed there is already a considerable amount of research on the impact of this in fetal animal models.

Segmental Approach to Echocardiography in Congenital Heart Disease

The following four echocardiographic steps of segmental analysis are crucial in any patient with CHD. Starting from a standard subcostal view, one should determine the position of the apex, the situs of the atria, and the AV and ventriculoarterial relationships.

1. *Apex position.* From a standard subcostal view, determine whether the apex of the heart is pointing to the right (dextrocardia), to the left (levocardia), or to the middle (mesocardia) (**Fig. 62-1**) (Videos 62-7 through 62-9).
2. *Situs of the atria* (**Fig. 62-2**). The right and left atria differ morphologically with regard to their appendages. A morphologic right atrium has a broad right atrial appendage, whereas a morphologic left atrium has a narrow left atrial appendage. Right and left atrial appendages, however, are difficult to visualize with transthoracic echocardiography, and one often has to rely on abdominal situs to determine atrial situs. Atrial situs follows abdominal situs in approximately 70% to 80% of cases. From a standard subcostal view with the probe pointing at a right angle to the spine, one can visualize the abdominal aorta, as well as the inferior vena cava and the spine at the back. When the aorta is to the left of the spine and the inferior vena cava to the right of the spine, abdominal situs solitus is present and, in all probability, corresponding atrial situs solitus (meaning the morphologic right atrium is on the right side and the morphologic left atrium is on the left side, the so-called usual atrial arrangement). In this setting the usual situation is for the systemic veins to connect to the morphologic right atrium and the pulmonary veins to the left (**Fig. 62-3**); however, systemic and pulmonary venous drainage does not define atrial morphology. When the aorta is to the right of the spine and the inferior vena cava is to the left of the spine, abdominal situs inversus is present and, in all probability, corresponding atrial situs inversus (morphologic right atrium on the left side and morphologic left atrium on the right side, i.e., "mirror-image" atrial arrangement). When both the aorta and inferior vena cava are on the same side of the spine, abdominal and atrial right isomerism is usually present (two morphologic right atria). Left atrial isomerism (two morphologic left atria) is generally suspected when the intrahepatic inferior vena cava is interrupted, along with the presence of azygos continuation in the paravertebral gutter on either the left or right side.
3. *AV relationship.* Once the situs of the atria is determined, one must assess the position of the ventricles in relation to the atria. The morphologic right ventricle has four characteristic features that distinguish it from the morphologic left ventricle: (1) a trabeculated apex, (2) a moderator band, (3) septal attachment of the tricuspid valve, and (4) lower (apical) insertion of the tricuspid valve. The tricuspid valve is always "attached" to the morphologic right ventricle (**Fig. 62-4** and see Video 62-8). The morphologic left ventricle has the following characteristics: (1) a smooth apex,

**VIDEO 62-7**

The image is taken from the subcostal view and shows a single left-sided AV valve, a flap foramen ovale, and sulcus tissue where the tricuspid valve should be.

VIDEO 62-8

This is a normal heart with AV concordance. Note the smooth left-sided morphologic left ventricle versus the heavily trabeculated right-sided morphologic right ventricle. In addition, the tricuspid valve is situated more inferiorly than its mitral counterpart.

VIDEO 62-9

This view is from a heart with AV discordance. Note that the left-sided morphologic right ventricle is heavily trabeculated with the tricuspid valve being inserted more inferiorly than the right-sided mitral valve.

FIGURE 62-1 Cardiac position. This montage demonstrates assessment of cardiac position in patients with complex CHD as obtained from the subcostal position in a coronal plane. This is the optimal plane to determine the position of the apex of the heart.

FIGURE 62-2 Montage of the different types of situs as seen on a subcostal echocardiographic scan. Note that situs solitus and inversus are just the mirror image of each other. The **upper right** picture is in the setting of heterotaxy with an interrupted intrahepatic inferior vena cava (IVC) and azygos (AZY) continuation on the *left*. This is seen more frequently with left atrial isomerism. The **lower right** picture is also in the setting of heterotaxy with an intrahepatic IVC that is positioned closer to the aorta (AO) than in solitus or inversus. Note also the midline liver. This pattern is seen more commonly in right atrial isomerism.

(2) no moderator band, (3) no septal attachment of the mitral valve, and (4) higher (basal) insertion of the mitral valve. The mitral valve is always “attached” to the morphologic left ventricle (see Fig. 62-4). Once the position of the ventricles is determined, one can then establish the AV relationship. When the morphologic right atrium empties into the morphologic right ventricle and the morphologic left atrium empties into the morphologic left ventricle, AV concordance is present. When the morphologic right atrium empties into the morphologic left ventricle and the morphologic left atrium empties into the morphologic right ventricle, AV discordance is present (see Fig. 62-4) (Video 62-10, and see Video 62-9).

- **Morphologic right ventricle.** A morphologic right ventricle is a triangular-shaped structure with an inlet, trabecular, and outlet

component. The inlet component of the right ventricle has attachments from the septal leaflet of the tricuspid valve. Inferior to this is the moderator band, which arises at the base of the trabeculoseptomarginalis, with extensive trabeculations toward the apex of the right ventricle. The outlet component of the right ventricle consists of a fusion of three structures (i.e., the infundibular septum separating the aortic from the pulmonary valve, the ventriculofundibular fold separating the tricuspid valve from the pulmonary valve, and finally, the anterior and posterior limbs of the trabeculoseptomarginalis).

- **Morphologic left ventricle.** A morphologic left ventricle is an elliptical-shaped structure with a fine trabecular pattern and absent septal attachments of the mitral valve in a normal heart. It consists of an inlet portion containing the mitral valve and a

**VIDEO 62-10**

This image, as seen from the subcostal position, shows the rightward apex and the morphologic right ventricle on the left side giving rise to the aorta. Note the heavily trabeculated morphologic right ventricle and the “compressed” low-pressure morphologic left ventricle.

FIGURE 62-3 Systemic and pulmonary venous drainage. This montage demonstrates systemic and pulmonary venous drainage in a heart with dextrocardia and a double-inlet left ventricle. The image on the **left** shows the superior vena cava connecting to the right-sided atrium. The **right** image shows the pulmonary veins draining to the left-sided atrium in the same case. LA = left atrium; LV = left ventricle; RA = right atrium.

FIGURE 62-4 AV concordance, AV discordance. The image on the **left** is from a heart with AV concordance. Note that the tricuspid valve is inserted at a lower level than the mitral valve. Also note the heavily trabeculated right ventricle with evidence of the moderator band. The image on the **right** is from a heart with AV discordance. Note in this image that the left-sided tricuspid valve is inserted at a lower level than its mitral counterpart. Also, the right-sided interventricular septum is smooth, with no septal attachments from the right-sided mitral valve. LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

FIGURE 62-5 Fifty percent rule straddling the left AV valve (LAVV). These two images are from a heart with dextrocardia and a double-inlet left ventricle. Note in the **left** panel that the LAVV annulus, as indicated by the white arrows, overrides the interventricular septum by at least 50%. If the overriding is less than 50%, the designation would be AV discordance. There is straddling of the LAVV, as indicated by the white arrows. The valve has a foot in both ventricles. This demonstrates one of the flaws in the nomenclature, that is, determining in this heart the precise amount of overriding. Of importance, the presence of the straddling valve plays no role in the designation of the AV connection. LA = left atrium; LV = left ventricle; PA = pulmonary artery; RA = right atrium; RV = right ventricle; S = interventricular septum.

tension apparatus, an apical trabecular zone that is characterized by fine trabeculations, and an outlet zone that supports the aortic valve.

- **Functionally single ventricle.** What happens when these basic rules do not apply? This is encountered in hearts in which both atria are predominantly connected to one ventricle (uni-ventricular AV connection), either by one or two AV valves. There has been recent consensus in the nomenclature such that these hearts are referred to as a “functionally single ventricle.” In general, these are hearts in which both ventricular chambers cannot be used to support the systemic and pulmonary venous circulations, with the only option being a Fontan approach. This approach has been the Rosetta stone of morphology in that it connects the European and North American classifications. Of note, in these hearts the apex can be left sided, midline, or on the right, none of which has an impact on the classification of a functionally single ventricle. In addition, they can coexist with all types of situs: solitus, inversus, or isomeric. Moreover, the type of ventriculoarterial connection does not influence this classification. It is possible to have normally related great arteries, discordant arterial connections, or a single outlet with either aortic or pulmonary atresia. When two ventricles are present, they are usually connected by a VSD, which in most cases is muscular in nature.

- **Double-inlet ventricle.** In these hearts both atria are connected mainly to one ventricular chamber, either by two valves or by a common AV valve. This is dictated by the 50% rule whereby more than 50% of the total annular circumference is committed to one ventricular mass, this being independent of the status of the AV valves (**Fig. 62-5**) (Videos 62-11 through 62-17). Of note, the designation double inlet is not dictated by the morphology or size of the connecting AV valves. They can connect mainly into a ventricle of left or right ventricular morphology and rarely one ventricle, the morphology of which can be difficult to determine (**Fig. 62-6**) (Video 62-18). The morphology of the ventricles is determined in part by some of the same features described earlier, but in a ventricular chamber without a connecting AV valve the position of that chamber relative to the larger one is an important key in determining its status as a left or right ventricle. For example, a smaller ventricle lying posterior to a larger one is almost always a morphologic left ventricle. A smaller ventricle lying anterior to a larger one is a morphologic right ventricle (**Fig. 62-7**) (Video 62-19).

Ventricular looping is also an important consideration. For example, in a double-inlet left ventricle, an L loop is more common with the morphologic left ventricle situated on the right of the hypoplastic morphologic right ventricle. In a D loop the morphologic left ventricle is on the left of the hypoplastic morphologic right ventricle (**Fig. 62-8**) (Videos 62-20 and 62-21).

- **Absent connection.** In these hearts there is absence of either the left- or right-sided AV valve, with a solitary valve connecting both atria to the main ventricular mass. These are often referred to as mitral or tricuspid atresia,

**VIDEO 62-11**

This subcostal image shows the apex directed to the right in a heart with a double-inlet left ventricle. Note the two AV valves opening into the left ventricle. The superior vena cava can be seen connecting with the right-sided atrium and some pulmonary veins to the left-sided atrium.

VIDEO 62-12

This subcostal sweep demonstrates the problem with the 50% rule. That is, if more than 50% of the left-sided AV junction is committed to the right-sided morphologic left ventricle, the heart is assigned as a double-inlet left ventricle. If on the other hand there is less than 50% commitment of that annulus, AV concordance would be present. The straddling left-sided tricuspid valve can be seen, as can the annular override of the left-sided AV valve. There is a large VSD and hypoplasia of the left-sided morphologic right ventricle.

VIDEO 62-13

This loop shows a double-inlet left ventricle with two AV valves. Note the pulmonary veins draining into the left-sided atrium.

VIDEO 62-14

This heart shows a double-inlet left ventricle with two AV valves opening into the left ventricle and with a hypoplastic anterior morphologic right ventricle. Note the large anterior muscular VSD.

VIDEO 62-15

This subcostal view shows a sweep in a heart with a double-inlet left ventricle and two AV valves with a hypoplastic right-sided morphologic right ventricle. The image is taken from the subcostal position. Note that the great vessels cross, with the aorta arising from the left-sided morphologic left ventricle and the pulmonary artery from the small right ventricle.

VIDEO 62-16

This subcostal view shows the apex pointing to the left in a heart with a double-inlet left ventricle and a hypoplastic right-sided morphologic right ventricle. In this case the aorta arises from the right-sided right ventricle and the pulmonary artery from the left ventricle. Note that there is a large VSD and a band around the pulmonary artery.

VIDEO 62-17

This image shows a double inlet into a morphologic right ventricle. Note that the two AV valves open into a heavily trabeculated right ventricle.

VIDEO 62-18

This image shows a double inlet into a ventricle that could be of right ventricular morphology or indeterminate if no other ventricle is identified to help in classification. There is a common atrium and a common AV valve. Note that the presence of the common AV valve does not affect the designation of a double inlet. A stent is protruding from a left-sided pulmonary vein into the common atrium.

VIDEO 62-19

This short-axis view shows a hypoplastic posterior morphologic left ventricle and a large anterior right ventricle. The very location of the large ventricle in relation to the hypoplastic one helps in ascertaining the definition.

VIDEO 62-20

This image, taken from the subcostal position, shows a heart with a left-sided apex and an L loop. That is, the morphologic right ventricle is to the left and anterior to the morphologic left ventricle. Note the smooth septal surface of the morphologic left ventricle. The heart has a single outlet that can be seen arising from the morphologic right ventricle. There is a large VSD with a common AV valve.

VIDEO 62-21

This heart has mesocardia-inverted ventricles, with the morphologic left ventricle being on the right and the right ventricle on the left. In addition, there is a common AV valve and a primum atrial defect.

FIGURE 62-6 Double-inlet labels. These three images are from hearts with a double inlet. The one on the **left** is from a heart with a double-inlet right ventricle (note the coarse trabeculations) and two AV valves that are totally committed to the large right ventricle. The image on the **right** is from a heart with a double-inlet left ventricle and two AV valves. Note the hypoplastic right ventricle on the right and the large VSD. The image in the **middle** is from a heart with a double inlet and a common AV valve with an associated common atrium (often seen in hearts with isomerism). There was no second chamber in the heart and the designation of a morphologic left or right ventricle is difficult. LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

FIGURE 62-7 Chamber position. These two images show how the position of the ventricles can help in determining their morphology. On the **left** side the larger chamber is posterior with the smaller one being anterior; thus the larger chamber is the morphologic left ventricle. The **right** panel demonstrates the opposite, that is, a dominant right ventricle with a smaller posterior left ventricle. LV = left ventricle; RV = right.

FIGURE 62-8 Ventricular looping. The image on the **left**, taken from the subcostal position, shows a heart with levocardia, a D loop, and a double-inlet left ventricle; that is, the morphologic left ventricle is on the right and the hypoplastic right ventricle is on the left. The panel on the **right**, taken from the subcostal position as well, is also from a heart with levocardia and a double-inlet left ventricle; however, there is an L loop, with the morphologic right ventricle being to the left of and anterior to the larger morphologic left ventricle. Of note, in the **left** panel the pulmonary artery arises from the right-sided right ventricle, whereas it arises from the morphologic left ventricle in the **right** panel. LV = left ventricle; PA = pulmonary artery; RV = right ventricle.

terminology that is still in common use (**Fig. 62-9**) (Videos 62-22 and 62-23; also see Video 62-7). Although the remaining AV valve is often referred to as a mitral or tricuspid valve, this can be misleading because in some instances, valve morphology does differ from the classic description in a normal heart. Of importance, the floor of the absent connection consists of sulcus tissue, such that if a pin were to be passed from the right atrium through that tissue, it would end up outside the heart and not in the hypoplastic left or right ventricle.

- *Functionally single ventricle in the setting of AV concordance or discordance, but with associated hypoplasia of one ventricle.* All these hearts require a Fontan or single-ventricle palliation as a result of the smaller ventricle being incapable of supporting either the systemic or pulmonary venous circulation. This includes hearts with the classic hypoplastic left heart syndrome, pulmonary atresia with an intact ventricular septum (**Fig. 62-10**) (Videos 62-24 and 62-25), unbalanced AV septal defects, and corrected transposition with hypoplasia of one or the other ventricle. Again, this classification is not affected by the status of the connecting AV valves or the ventriculoarterial connections.

4. *Ventriculoarterial relationship.* Once the AV relationship has been determined, one should assess the position of the great artery or arteries in relation to the ventricles (**Figs. 62-11 and 62-12**) (see Videos 62-10, 62-15, 62-16, and 62-20). It is possible to have an aorta and pulmonary artery or a solitary outlet from either ventricle, with the other artery being atretic. Also, in some cases the solitary outlet can be a solitary trunk that gives rise to the head and neck vessels, the pulmonary and coronary arteries. The pulmonary artery can be distinguished by its early branching pattern into the left and right pulmonary arteries; the pulmonary valve is always “attached” to the pulmonary artery. Similarly, the aorta can be distinguished by its “candy cane” shape and the take-off of its three head and neck vessels (innominate, carotid, and subclavian arteries).

**VIDEO 62-22**

This subcostal view shows a morphologic left ventricle on the left and a hypoplastic morphologic right ventricle on the right.

VIDEO 62-23

This loop shows a heart with levocardia and an absent right connection (tricuspid atresia). Note the sulcus tissue where the tricuspid valve should be situated, the latter separating the right atrium from the ventricular mass.

VIDEO 62-24

Heart with AV concordance but a hypoplastic right-sided morphologic right ventricle. This can be classified as a functional single ventricle, and the patient would need to undergo a Fontan operation.

VIDEO 62-25

This image is from a patient with hypoplastic left heart syndrome in which the left-sided morphologic left ventricle is too small to support the systemic circulation. Despite this, the AV connection is concordant, as was the ventriculoarterial connection. Nonetheless, it is classified “functionally” as a single ventricle, and the patient would require a Fontan operation.

FIGURE 62-9 Absent right connection labels. These two images are from hearts with an absent right connection, the one on the **left** with associated dextrocardia and the one on the **right** with levocardia. Note the pulmonary veins draining into the left atrium and the wedge of sulcus tissue between in the floor of the right atrium as seen on both images. If a pin were passed from the right atrium through the sulcus tissue, it would end up outside the heart in the AV groove, thus differentiating this from an imperforate valve. Also note the hypoplastic right ventricle on the right of the dominant left ventricle in the **right** panel. LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle; ST = sulcus tissue.

FIGURE 62-10 Unbalanced ventricles. The image on the **left** is from a heart with AV concordance but a hypoplastic morphologic right ventricle. Note that the tricuspid valve is perforate inasmuch as color Doppler shows some tricuspid valve regurgitation. This heart is from a person with pulmonary atresia and an intact ventricular septum. The heart on the **right** is from a person with hypoplastic left heart syndrome and a hypoplastic left-sided morphologic left ventricle. The AV connection is concordant. In both cases they are referred to as a “functionally single ventricle” because the small chamber cannot support either the systemic or pulmonary arterial circulation. LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

FIGURE 62-11 Ventriculoarterial concordance. These two images are from a heart with an absent right connection (tricuspid atresia) and ventriculoarterial concordance. That is, the aorta arises from the morphologic left ventricle and the pulmonary artery from the more anterior morphologic right ventricle. AO = aorta; LA = left atrium; LV = left ventricle; PA = pulmonary artery; RV = right ventricle.

The aortic valve is always “attached” to the aorta. Once the position of the great arteries is determined, one can establish the ventriculoarterial relationship. When the morphologic right ventricle ejects into the pulmonary artery and the morphologic left ventricle ejects into the aorta, ventriculoarterial concordance is present. When the morphologic right ventricle ejects into the aorta and the morphologic left ventricle ejects into the pulmonary artery, ventriculoarterial discordance is present. When more than 50% of both great arteries exit from one ventricle (right or left), it is called a *double-outlet* (right or left) *ventricle*.

Once segmental analysis has been completed, one can proceed to the usual echocardiographic windows to determine the nature of the specific lesions, as well as their hemodynamic relevance.

Other Echocardiographic Imaging Modalities

Transesophageal and Three-Dimensional Echocardiography

Transesophageal echocardiography (TEE) offers better two-dimensional resolution than transthoracic echocardiography does. This is especially important in adult patients with multiple previous cardiac operations, in whom adequate transthoracic windows are often difficult to obtain.

TEE should be used whenever transthoracic echocardiography and/or MRI do not provide adequate anatomic or functional information. The addition of real-time three-dimensional TEE has opened a new window in this age group.¹³ Transthoracic three-dimensional echocardiography has been disappointing in the adult CHD population because of patient size and previous operations; however, its TEE counterpart can play a major role in diagnostic evaluation. TEE should be considered in the setting of the conditions discussed in the following sections.

Secundum Atrial Septal Defect. Use TEE for evaluating the feasibility of device closure, measuring ASD size, assessing the adequacy of margins for anchoring the device, and ruling out an anomalous pulmonary venous connection. This information can be enhanced by real-time three-dimensional imaging, which provides precise anatomic detail of the ASD (**Fig. 62-13**).

Atrioventricular Valve Regurgitation. Use TEE for preoperative evaluation of mitral valve leaflet morphology and suitability for mitral valve repair versus replacement. Real-time three-dimensional TEE is rapidly becoming the reference standard for evaluating mitral valve form and function before surgical or catheter intervention.²⁵ In addition, such imaging is invaluable in patients with complex CHD and abnormalities in one or other AV valve. Lesions such as a postoperative AV septal defect or corrected transposition (**Fig. 62-14**, and Videos 62-26 and 62-27) or those after the Fontan procedure with a regurgitant systemic AV valve frequently require further intervention. Although real-time three-dimensional TEE has been disappointing for assessment of the tricuspid valve in those with normal connections and no ventricular hypoplasia, such has not been the case in hearts after a Fontan procedure because invariably the valve being evaluated is more perpendicular to the ultrasound beam, unlike the situation with a normal tricuspid valve, where it is oblique, which affects image resolution. Preoperative planning via imaging plus real-time

**VIDEO 62-26**

This transesophageal real-time three-dimensional image shows a left-sided AV valve in a patient who had previously undergone repair of an AV septal defect. The image is viewed from the left ventricular aspect. Note the small residual cleft in the left AV valve and the hole in the valve near the septal surface. There is some dropout of the more anterior right-sided AV valves because the focus of the image was on the left-sided valve.

VIDEO 62-27

This transesophageal real-time three-dimensional image is from the same case as the “three-dimensional left AV valve preoperative” case (Video 62-26) and shows the two sites of left AV valve regurgitation in this patient. One location is at the hole in the valve and the other at the site of coaptation of the leaflets, which is more central. These two sites are indicated by the two *white arrows*. RV = right ventricle.

FIGURE 62-12 Ventriculoarterial discordance. These two images are from different hearts, one with a hypoplastic aorta (**right panel**) and the other with a hypoplastic main pulmonary artery (**left panel**). Note in both cases that the aorta is anterior to the posterior pulmonary artery. The image on the **left** shows the two great arteries, which are parallel to each other. The image on the **right** is taken in the short-axis plane. AO = aorta; LA = left atrium; LV = left ventricle; PA = pulmonary artery; RV = right ventricle; SVC = superior vena cava.

FIGURE 62-13 Three-dimensional secundum ASD. This real-time three-dimensional echocardiographic image obtained by TEE demonstrates the rims of a large secundum ASD, as seen from the right atrium. IVC = inferior vena cava, SVC = superior vena cava.

FIGURE 62-14 Three-dimensional postoperative AV septal defect (AVSD). This TEE real-time three-dimensional image is taken from below in a patient following repair of an AVSD. It images the left AV valve from below and demonstrates two mechanisms of regurgitation, one from an area of dehiscence of the valve indicated by the **black arrow** and the second centrally caused by poor coaptation of the leaflets. LAVV = left AV valve; LVOT = left ventricular outflow tract; RAVV = right AV valve.

three-dimensional color Doppler is essential for an optimal repair (**Fig. 62-15** and Video 62-28). Color Doppler assessment of the site of regurgitation is more sensitive than standard saline testing²⁵ and thus should be used in each case.

Ebstein Anomaly. Use TEE for preoperative assessment of tricuspid valve morphology and the potential for tricuspid valve repair. Thus far, real-time three-dimensional echocardiography has been disappointing in imaging this lesion because the leaflets are often so thin that there are too many areas of dropout in the images.

Clot Assessment. Use TEE when a right atrial clot is suspected after the Fontan procedure on clinical grounds or by transthoracic echocardiography or when circuit obstruction is suspected.

Before Cardioversion. For any patient who is not anticoagulated and has experienced atrial flutter or fibrillation for longer than 24 hours, TEE should be performed before chemical or electrical cardioversion. Patients with a Fontan circuit should undergo TEE irrespective of the duration of atrial tachyarrhythmia to rule out a right or left atrial thrombus.

Guidance for Therapeutic Intervention. Both standard two-dimensional TEE and, more recently, real-time three-dimensional TEE can be instrumental in helping guide therapy at the time of transcatheter or surgical procedures. TEE is particularly helpful in the following situations.

Closure of a Percutaneous Device. TEE is performed at the time of transcatheter ASD closure to assist in ASD-stretched balloon sizing and device deployment unless intracardiac echocardiography (ICE) (see later) is available.

Assessment of Ventricular Volume. Real-time three-dimensional echocardiography has already been demonstrated to provide accurate data with regard to left ventricular volume and function, and more recently, albeit in younger populations, the same technology has been applied quite successfully to the right ventricle, in particular, in the post-tetralogy of Fallot population.²⁶

Intracardiac Echocardiography. ICE uses lower-frequency transducers that have been miniaturized and mounted into catheters capable of percutaneous insertion into the heart.²⁷ ICE not only provides high-resolution two-dimensional and hemodynamic data with full Doppler capabilities but also eliminates the need for general anesthesia, which is often required for TEE. Two specific areas where ICE is useful are:

Percutaneous Device Closure of an Atrial Septal Defect. ICE supports percutaneous device closure of an ASD by adequately sizing the defect and assisting in device positioning while avoiding the need for general anesthesia. More recently, real-time three-dimensional TEE is being used to not only assess the size and suitability for device closure of an ASD but also to monitor the procedure, either in an interventional setting, or surgically using robotic procedures.²⁸

Electrophysiologic Studies. ICE assists in electrophysiologic procedures by guiding transseptal puncture, enabling endocardial visualization, and ensuring electrode-tissue contact at the time of ablative procedures. Recently, a forward-looking imaging and ablation probe has been developed that will enable precise localization of energy delivery to an arrhythmogenic focus²⁹ (see Chapter 34).

Cardiac Catheterization

With the development of cross-sectional echocardiography and the subsequent introduction of MRI and fast computed tomography (CT) methods, truly diagnostic cardiac catheterization (see Chapter 19) is becoming rare. “Diagnostic” catheterization is reserved for resolving unanswered questions from the less-invasive techniques and for measuring hemodynamics. A good example of this is

**VIDEO 62-28**

These four images were obtained from multiplane reformatting of the tricuspid valve. In the **lower right** panel the three-dimensional en face image of the tricuspid valve can be seen. The hypoplastic mitral valve can also be seen in the **upper left** part of this image. The other three images are cuts of this three-dimensional image. The one immediately above the three-dimensional image is the *red* plane, as noted by the outline of the box in which it is situated. The *green* line represents the level of the cut seen on the three-dimensional image. The **upper** image with the *green* box surround is an image seen in that plane, and the *red* line is the level of the cut as seen on the three-dimensional image. The *blue* box shows the en face view of the tricuspid valve. The three-dimensional image shows the tethered tricuspid septal leaflet and some prolapse of the anterior leaflet.

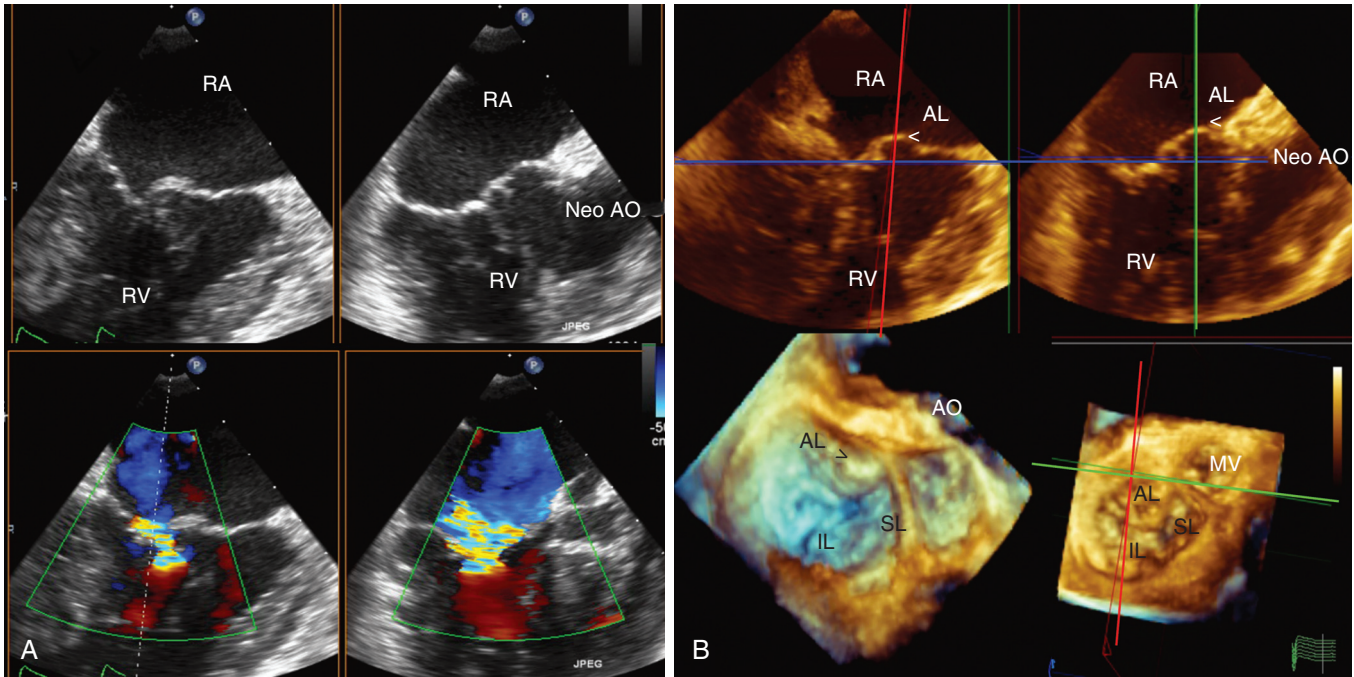

FIGURE 62-15 Three-dimensional tricuspid valve after a Fontan procedure. The TEE image labeled **A** demonstrates moderate tricuspid valve regurgitation after a Fontan procedure in a patient with hypoplastic left heart syndrome and dextrocardia. Although the moderate regurgitation is evident from the color Doppler signal, the precise mechanism and location are unclear. The real-time three-dimensional echocardiographic image labeled **B** displays the tricuspid valve in the multiplane reformatting mode, as well as a surgical en face view of the tricuspid valve. The *red* and *green* lines are at right angles to each other and show that the main problem is prolapse of the anterior leaflet of the tricuspid valve. The *lower right* image is in the exact spatial location as the upper two images, whereas the *lower left* image has been angled to show the prolapse in more detail. Although not seen from the surgical en face view, the position of the aorta has been noted to help in orientation. AL = anterior leaflet; AO = aorta; IL = inferior leaflet; MV = mitral valve; RA = right atrium; RV = right ventricle; SL = septal leaflet.

assessment of the major aortopulmonary collateral arteries in patients with tetralogy of Fallot and pulmonary atresia, in whom their presence and distribution may be shown beautifully by magnetic resonance angiography (MRA), but cardiac catheterization may be required to demonstrate the presence of communications with the central pulmonary arteries and to measure the pressure within them. There is no adequate substitute for cardiac catheterization to measure ventricular end-diastolic pressure or pulmonary artery pressure and resistance with the precision required to plan for or assess the Fontan circulation. Furthermore, diagnostic testing may also be needed to evaluate possible coronary artery disease, especially before heart surgery in adults.

Therapeutic Catheterization

Balloon atrial septostomy was the first catheter intervention that proved useful in treating heart disease, and it remains the standard initial palliation in many infants with D-TGA. Many transcatheter techniques are now used successfully to treat CHD: blade atrial septostomy; device or coil closure of PDA; closure of ASD and patent foramen ovale (PFO); transluminal balloon dilation of pulmonary and aortic valve stenosis; radiofrequency perforation of pulmonary valve atresia; balloon-expandable intravascular stents for right ventricular outflow tract, pulmonary artery, aortic coarctation, and other vascular stenoses; and device occlusion of unwanted collateral vessels and AV fistulas. These have all become treatments of choice in centers with these capabilities. Some are universally accepted as the standard of care (e.g., balloon pulmonary valvuloplasty), whereas debate continues for other interventions (e.g., unoperated coarctation). One of the most exciting new developments has been transcatheter valved stents for the treatment of right ventricular outflow stenosis and regurgitation in patients with congenital defects, a procedure that also has led to an explosion of transcatheter valve techniques for acquired disease. Going along with the extraordinary expansion of interventional techniques for the treatment of structural abnormalities, ablative techniques for the treatment of tachycardias are now performed routinely in centers with congenital

heart electrophysiology programs and are crucial in the management of adults with operated and unoperated CHD, in whom arrhythmias are such a burden in terms of their morbidity, as well as a significant cause of late mortality. The indications, outcomes, and current status of each of these techniques are discussed later in detail in the sections covering specific lesions.

SPECIFIC CARDIAC DEFECTS

Left-to-Right Shunts

Atrial Septal Defect

Morphology

Four types of ASDs or interatrial communications exist: ostium primum, ostium secundum, sinus venosus, and coronary sinus defects (**Fig. 62-16A and D**) (Videos 62-29 and 62-30). (Ostium primum is discussed in the section on AV septal defect.) Ostium secundum defects occur as a result of either excessive resorption of the septum primum or deficient growth of the septum secundum and are occasionally associated with an anomalous pulmonary venous connection (<10%). Sinus venosus defects of the superior vena cava type occur at the cardiac junction of the superior vena cava and give rise to a superior vena cava connected to both atria; they are almost always associated with an anomalous pulmonary venous connection (right >> left) (see **Fig. 62-16D**). Sinus venosus–inferior vena cava-type defects are very uncommon and abut the junction of the inferior vena cava inferior to the fossa ovalis. Coronary sinus septal defects are rare and arise from an opening of its wall with the left atrium, thereby allowing left-to-right atrial shunting.

Pathophysiology

In any type of ASD, the degree of left-to-right atrial shunting depends on the size of the defect and the relative diastolic filling properties of the two ventricles. Any condition causing reduced left ventricular compliance (e.g., systemic hypertension, cardiomyopathy, myocardial infarction) or increased left atrial pressure (mitral stenosis

**VIDEO 62-29**

Coronary sinus defect. This loop shows a large coronary sinus defect with an intact atrial septum. Note how inferior the defect is.

VIDEO 62-30

Coronary sinus defect. This real-time three-dimensional echocardiogram as seen from the right atrial aspect shows the large coronary sinus defect.

A

C

B

D

FIGURE 62-16 **A**, Schematic diagram outlining the different types of interatrial shunting that can be encountered. Note that only the central defect is suitable for device closure. **B**, Subcostal right anterior oblique view of a secundum ASD (asterisk) that is suitable for device closure. The right panel is a specimen seen a similar view that is outlining the landmarks of the defect. **C**, The left image is a transesophageal echocardiogram with color flow before device closure, whereas the right side shows an Amplatzer device after release. **D**, Montage of interatrial communications that are not ASDs (asterisks) and therefore not suitable for device closure. The upper left is a coronary sinus defect caused by unroofing, the top right is a superior sinus venosus defect, the bottom left is an inferior sinus venosus defect, and the bottom right is an ASD in the setting of an AV septal defect. AO = aorta; CS = coronary sinus; Eust = eustachian; IVC = inferior vena cava; LA = left atrium; LV = left ventricle; RA = right atrium; SVC = superior vena cava; Tric = tricuspid.

and/or regurgitation) tends to increase the left-to-right shunt. If similar forces are present in the right side of the heart, this will diminish the left-to-right shunt and promote right-to-left shunting.

Natural History

A large ASD (pulmonary artery blood flow relative to systemic blood flow [Q_p/Q_s] $>2.0:1.0$) may cause congestive heart failure and failure to thrive in an infant or child. An undetected ASD with a significant shunt ($Q_p/Q_s >1.5:1.0$) probably causes symptoms over time in adolescence or adulthood, and symptomatic patients usually become progressively more physically limited as they age. Effort-related dyspnea is seen in approximately 30% of patients by the third decade and in more than 75% by the fifth decade. Exercise intolerance on cardiopulmonary testing is even more common and reflects the fact that such patients often do not know what "normal" feels like. Supraventricular arrhythmias (atrial fibrillation or flutter) and right-sided heart failure develop by 40 years of age in approximately 10% of patients and become more prevalent with aging. Paradoxical embolism resulting in a transient ischemic attack or stroke can call attention to the diagnosis. The development of pulmonary hypertension, although probably not as common as originally thought, can occur at an early

age. If pulmonary hypertension is severe, a second causative diagnosis should be sought. Life expectancy is clearly reduced in patients with an ASD, although not as severely as was quoted in earlier papers because only patients with large ASDs were reported.

Clinical Features

Symptoms are rare in childhood, and the decision to close an ASD is usually based on the presence of right-sided heart volume overload and as prophylaxis against later adverse outcomes in patients with a significant defect (>10 mm). The most common initial symptoms in adults are exercise intolerance (exertional dyspnea and fatigue) and palpitations (typically from atrial flutter, atrial fibrillation, or sick sinus syndrome). Right ventricular failure can be the initial symptom in older patients. The presence of cyanosis should alert one to the possibility of shunt reversal and Eisenmenger syndrome or, alternatively, to a prominent eustachian valve directing inferior vena cava flow to the left atrium via a secundum ASD or sinus venosus ASD of the inferior vena cava type.

Examination shows "left atrialization" of jugular venous pressure (A wave = V wave). A hyperdynamic right ventricular impulse may be felt at the left sternal border at the end of expiration or in the

subxiphoid area on deep inspiration. A dilated pulmonary artery trunk may be palpated in the second left intercostal space. A wide and fixed split of S_2 is the auscultatory hallmark of ASD, although it is not always present. A systolic ejection murmur, usually grade 2 and often scratchy, is best heard at the second left intercostal space, and a mid-diastolic rumble, from increased flow through the tricuspid valve, may be present at the left lower sternal border. When right ventricular failure occurs, a pansystolic murmur of tricuspid regurgitation is usual.

Laboratory Investigations

Electrocardiogram. Sinus rhythm or atrial fibrillation or flutter may be present. The QRS axis is typically rightward in secundum ASD, and “crotchetage” of the QRS complex may be seen in the inferior leads. Negative P waves in the inferior leads indicate a low atrial pacemaker, often seen in sinus venosus–superior vena cava–type defects, which are located in the area of the sinoatrial node and render it deficient. Complete right bundle branch block appears as a function of age. Tall R or R' waves in V_1 frequently indicate pulmonary hypertension.

Chest Radiography. The classic radiographic features are cardiomegaly (from right atrial and right ventricular enlargement), dilated central pulmonary arteries with pulmonary plethora indicating increased pulmonary flow, and a small aortic knuckle (reflecting a chronic low–cardiac output state).

Echocardiography (Videos 62-31 and 62-32). Transthoracic echocardiography can be used to document the types and sizes (defect diameter) of ASDs, the directions of the shunts (Fig. 62-16B), and sometimes the presence of anomalous pulmonary venous return. The functional importance of the defect can be estimated by the size of the right ventricle, the presence or absence of right ventricular volume overload (paradoxical septal motion), and (less accurately) estimation of Q_p/Q_s . Indirect measurement of pulmonary artery pressure can be obtained from the Doppler velocity of the tricuspid regurgitation jet. TEE permits better visualization of the interatrial septum and is usually required when device closure is contemplated, partly to ensure that pulmonary venous drainage is normal. ICE can be used instead of TEE during device closure to help guide insertion of the device, thereby reducing fluoroscopic and procedural time and forgoing the need for general anesthesia.

Indications for Intervention

Shunt fractions are now rarely measured and are reserved for “borderline” cases. Hemodynamically insignificant ASDs ($Q_p/Q_s < 1.5$) do not require closure, with the possible exception of attempts to prevent paradoxical emboli in older patients after a stroke. “Significant” ASDs ($Q_p/Q_s > 1.5$ or ASDs associated with right ventricular volume overload) should be closed, especially if device closure is available and appropriate. For patients with pulmonary hypertension (pulmonary artery pressure $> \frac{2}{3}$ systemic arterial blood pressure or pulmonary arteriolar resistance $> \frac{2}{3}$ systemic arteriolar resistance), closure can be recommended if there is a net left-to-right shunt of at least 1.5:1 or evidence of pulmonary artery reactivity when challenged with a pulmonary vasodilator (e.g., oxygen or nitric oxide).

DEVICE CLOSURE. Device closure of secundum ASDs percutaneously under fluoroscopy and TEE or with ICE guidance is the therapy of choice when appropriate (Fig. 62-16C and Video 62-33). Indications for device closure are the same as for surgical closure, but the selection criteria are stricter. Depending on the device, this technique is available only for patients with a secundum ASD that has a stretched diameter of less than 41 mm and adequate rims to enable secure deployment of the device. Anomalous pulmonary venous connection or proximity of the defect to the AV valves or coronary sinus or systemic venous drainage usually precludes the use of this technique. It is a safe and effective procedure in experienced hands, with major complications (e.g., device embolization, atrial perforation, thrombus formation) occurring in less than 1% of patients and clinical closure achieved in more than 80%. Device closure of an ASD improves functional status in symptomatic patients independent of age^{30,31} and exercise capacity in asymptomatic and symptomatic patients. Intermediate follow-up data have proved device closure of ASDs to be safe and effective,³² with better preservation of right ventricular function and lower complication rates than reported with surgery.

SURGERY. Device closure is not an option for those with sinus venosus or ostium primum defects or with secundum defects with unsuitable anatomy. ASDs can be closed surgically by primary suture closure or by applying a pericardial or synthetic patch. The procedure is generally performed via a midline sternotomy, but the availability of an inframammary or minithoracotomy approach to a typical secundum ASD should be made known to cosmetically sensitive patients. Surgical mortality in adults without pulmonary hypertension should be less than 1%. Surgical closure of an ASD improves functional status and exercise capacity in symptomatic patients, improves (but usually does not normalize) survival, and improves or eliminates congestive heart failure, especially when patients undergo surgery at an earlier age. However, surgical closure of ASDs in adult life does not prevent atrial fibrillation/flutter or stroke, especially when patients undergo surgery after the age of 40 years. The role of a concomitant Cox-maze procedure in patients with a previous history of atrial flutter or fibrillation should be considered (see Chapters 33, 35, and 38). In the setting of preexisting atrial tachyarrhythmias, surgical as well as device closure of an ASD does decrease the incidence of postoperative atrial tachyarrhythmia.³³⁻³⁵

Reproductive Issues

Pregnancy is well tolerated in patients after ASD closure. It is also well tolerated in women with unrepaired ASDs, but the risk for paradoxical embolism is increased (still only very low risk) during pregnancy and in the postpartum period. Pregnancy is contraindicated in those with Eisenmenger syndrome because of high maternal ($\approx 50\%$) and fetal ($\approx 60\%$) mortality.

Follow-Up

After device closure, patients require 6 months of aspirin and endocarditis prophylaxis until the device endothelializes, following which, assuming that no residual shunt is present, they do not require any special precautions or endocarditis prophylaxis. Patients with sinus venosus defects are at risk for the development of caval and/or pulmonary vein stenosis and should be kept under intermittent review. Patients who have undergone surgical or device repair as adults, patients with atrial arrhythmias preoperatively or postoperatively, and those with ventricular dysfunction should remain under long-term cardiology surveillance. Indeed, all patients who have undergone device closure should probably have an echocardiogram taken every 5 years or so because of the possibility of late issues, especially erosion.

Patent Foramen Ovale

Anatomy

The foramen ovale is a tunnel-like space between the overlying septum secundum and septum primum and typically closes in 75% of people at birth by fusion of the septum primum and secundum. In utero the foramen ovale is necessary for flow of blood across the fetal atrial septum. Oxygenated blood from the placenta returns to the inferior vena cava, crosses the foramen ovale, and enters the systemic circulation. In approximately 25% of people a PFO persists into adulthood. PFOs may be associated with atrial septal aneurysms (a redundancy of the interatrial septum), eustachian valves (a remnant of the sinus venosus valve), and Chiari networks (filamentous strands in the right atrium).

Pathophysiology. PFOs have recently been scrutinized for their implication in the mechanism of cryptogenic stroke. Many of the basic tenets linking PFO and stroke seem plausible but have not been demonstrated. The current views may be summarized as follows. PFOs may serve as either a conduit for paradoxical embolization from the venous side to the systemic circulation or, because of their tunnel-like structure and propensity for stagnant flow, may serve as a nidus for in situ thrombus formation. Variation in PFO size, right atrial anatomy, varying hemodynamic conditions, and occurrence of venous thrombi may all contribute to the chance of paradoxical embolization developing. Risk for a cryptogenic stroke seems to be increased with larger PFOs. The presence of an interatrial septal aneurysm in combination with a PFO also increases the risk for an adverse event, perhaps

**VIDEO 62-31**

Sinus venosus defect. This right anterior oblique view, taken from the subcostal position, shows a large sinus venosus defect.

VIDEO 62-32

Sinus venosus defect. The left-to-right shunting is seen through the sinus venosus defect.

VIDEO 62-33

because of increased in situ thrombus formation in the aneurysmal tissue or simply because PFOs associated with an interatrial septal aneurysm tend to be larger. Eustachian valves and a Chiari network may direct blood flow from the inferior vena cava toward the atrial septum, thereby encouraging right-to-left shunting in the presence of an interatrial communication. Physiologic (Valsalva maneuvers) and pathologic conditions increasing right ventricular pressure will raise right atrial pressure and favor right-to-left shunting. Finally, pelvic vein thrombi are found more frequently in young patients with cryptogenic stroke than in those with a known cause of stroke and may provide the source of venous thrombi.

PFOs have also been implicated in the pathophysiology of decompression sickness (arterial gas embolism from the venous side), as well as in the pathogenesis of migraine headaches. Platypnea-orthodeoxia syndrome (dyspnea and arterial desaturation in the upright position that improves when lying down) has also been attributed to the presence of a PFO (Video 62-34).

Clinical Impact

The cause-and-effect relationship between PFO and cryptogenic stroke is still tentative and needs clarification. The recent body of literature would suggest a strong association, if not a causative link, especially in younger patients. Indeed, young patients with cryptogenic stroke have a significantly higher incidence of PFO (36% to 54%) than do normal controls (15% to 25%). The association is more controversial in the older patient population. Older patients often have more risk factors for stroke, and the causative role of a PFO in these patients is more difficult to establish.

When a patient is evaluated for stroke and a PFO is discovered, the usual causes of stroke must first be eliminated. Potential causes of strokes include carotid artery disease, ascending aortic atherosclerosis, atrial fibrillation, neurovascular abnormalities, and/or prothrombotic tendencies. If after an exhaustive investigation (see later) no other cause of the stroke can be found, the PFO may be considered to have possibly had a causative role. The diagnosis of a PFO as a cause of cryptogenic stroke is, at best, a diagnosis of exclusion.

Investigations. A PFO is usually detected by transthoracic echocardiography, TEE, or transcranial Doppler. TEE is the most sensitive test, especially when performed with contrast media injected during a cough or Valsalva maneuver. A PFO is judged to be present if microbubbles are seen in the left-sided cardiac chambers within three cardiac cycles from the maximum right atrial opacification.

Screening for prothrombotic states (e.g., protein C or S deficiency, antithrombin III, or lupus anticoagulant), atrial fibrillation, significant carotid atherosclerosis by carotid Doppler imaging, and neurovascular abnormalities by brain MRA must be undertaken in each patient before PFOs can be considered a possible culprit.

Therapeutic Options

Once the presumptive diagnosis of a cryptogenic stroke caused by a PFO is determined, treatment modalities to prevent recurrent events include antiplatelet or anticoagulant agents, percutaneous device closure, or surgical PFO closure. Medical therapy for secondary prevention of stroke with warfarin (Coumadin) or antiplatelet agents is often used as “first-line” therapy with similar efficacy and a yearly recurrence rate of approximately 2%. Patients with a PFO and atrial septal aneurysm who have experienced strokes seem to be at higher risk for recurrent stroke (as high as 15% per year), and a preventive strategy other than aspirin or Coumadin should perhaps be considered. Device closure is safe and seems to be effective, with a stroke recurrence rate of between

0% and 3.8% per year. Surgical closure of PFOs is usually performed when cardiac surgery is required for other reasons.

The Closure 1 trial, a randomized clinical trial comparing the STARFlex device with medical treatment (acetylsalicylic acid [ASA] or warfarin) in patients with a PFO after a stroke, did not show a significant difference between the two treatment arms regarding the recurrent stroke rate at a mean follow-up of 2 years.³⁶ A 2012 randomized trial comparing Amplatzer device closure and medical therapy (ASA or warfarin) showed a trend for device closure faring better than medical therapy, especially in patients with larger PFOs and/or an aneurysm.³⁷

A recent meta-analysis of transcatheter closure versus medical therapy for PFO in the prevention of recurrent neurologic events (RNEs) after presumed paradoxical embolism offers an overview of the literature as of July 2012.³⁸ The adjusted incidence rates of RNEs were determined. Transcatheter closure was found to be superior to medical therapy in the prevention of RNEs after cryptogenic stroke. In the medical arm, patients taking Coumadin had a lower recurrence rate than did those receiving antiplatelet therapy. After transcatheter closure, RNEs did not seem to be related to pretreatment shunt size or to the presence of residual shunting in the follow-up period. Transcatheter PFO closure was also beneficial in elderly patients, those with concomitant atrial septal aneurysm, and patients with thrombophilia. Further randomized controlled trials are needed to conclusively compare these two management strategies. Another paper from 2012 reviewed the current state of knowledge related to PFOs and highlighted gaps in our understanding.³⁹

Atrioventricular Septal Defect

Terminology

The terms *AV septal defect*, *AV canal defect*, and *endocardial cushion defect* can be used interchangeably to describe this group of defects. The variable components of these lesions are explained in the following sections.

Morphology. The basic morphology of an AV septal defect is common to all types and is independent of the presence or absence of an ASD or VSD; it includes a common AV junction with absence of the membranous and muscular AV septum (resulting in the AV valves being at the same level on echocardiography), inlet/outlet disproportion (resulting in an elongated left ventricular outflow tract, the so-called gooseneck deformity), abnormal lateral rotation of the posteromedial papillary muscle, and abnormal configuration of the AV valves (**Figs. 62-17** and **62-18**). The left AV valve is a trileaflet

FIGURE 62-17 Apical four-chamber view of a complete AV septal defect with a common AV valve orifice (asterisk). Note the large interatrial and interventricular communications and the large free-floating superior bridging leaflet. LA = left atrium; LV = left ventricle; RA = right atrium; RV = right ventricle.

**VIDEO 62-34**

Platypnea-orthodeoxia developed in a middle-aged man after pneumonectomy. When contrast material is injected from the inferior vena cava, a billowing atrial septum is seen transmitting contrast material to the left atrium. This is closed with an Amplatzer (St. Jude Medical Inc., St. Paul, Minn) PFO 35-mm device.

FIGURE 62-18 Montage comparing the normal AV junction with that seen in a patient with an AV septal defect (AVSD). The **upper left** picture is the normal AV junction as seen from above. Note the normal morphology of the mitral and tricuspid valves, with the aorta wedged between them. The **upper right** picture is a similar view of an AVSD. Note the unwedged aorta, the trileaflet left AV valve, and the cleft between the superior and inferior bridging leaflets. The **lower left** picture is a specimen of an AVSD demonstrating the cleft. The **lower right** picture is an echocardiogram showing the cleft. AO = aorta; LA = left atrium; LAV = left AV valve; MV = mitral valve; PA = pulmonary artery; RAV = right AV valve; RV = right ventricle; TV = tricuspid valve; * = cleft.

composed of superior and inferior bridging leaflets separated by a mural leaflet. The space between the superior and inferior leaflets as they bridge the interventricular septum is called the *cleft* in the left AV valve (Videos 62-35 through 62-38). The bridging leaflets may be completely adherent to the crest of the interventricular septum, free floating, or attached by a chordal apparatus.

Partitioned Versus Complete Atrioventricular Septal Defects. A *partitioned* orifice is one in which the superior and inferior leaflets are joined by a connecting tongue of tissue as they bridge the interventricular septum. This partitions the valve into separate left and right orifices. A *common* AV valve orifice is one with no such connecting tongue, which results in one large orifice that encompasses the left- and right-sided components. Interatrial (ostium primum) and interventricular defects are common in patients with AV septal defects.

The left ventricular outflow tract is elongated and predisposes to subaortic stenosis. The papillary muscles are closer together than normal. The term *unbalanced AV septal defect* refers to cases in which one ventricle is hypoplastic (Videos 62-39 through 62-41). This is seen more commonly in patients with heterotaxy and in those with left-sided obstructive defects.

Pathophysiology

Native. The pathophysiology of those with an isolated shunt at the atrial level (commonly referred to as a *primum ASD*) is similar to those with a large secundum ASD: unrestricted left-to-right shunting through the primum ASD leading to right-sided atrial and ventricular volume overload. Chronic left AV valve regurgitation may produce left-sided ventricular and atrial volume overload. A complete AV septal defect has a greater degree of left-to-right shunting from the primum ASD, as well as a nonrestrictive VSD, which triggers earlier left ventricular dilation and a greater degree of pulmonary hypertension.

After Correction. Residual significant left AV valve regurgitation may occur and cause significant left atrial as well as left ventricular dilation. Left AV valve stenosis from overzealous repair of the valve may also occur. The long, narrow left ventricular outflow tract of an AV septal defect promotes left ventricular outflow tract obstruction and leads to subaortic stenosis in approximately 5% of patients.

Natural History

Patients with an isolated primum ASD have a course similar to that of those with large secundum ASDs, although symptoms may appear sooner when significant left AV valve regurgitation is present. Patients may be asymptomatic until their third or fourth decade, but progressive symptoms related to congestive heart failure, atrial arrhythmias, complete heart block, and variable degrees of pulmonary hypertension develop in virtually all of them by the fifth decade.

Most patients with a complete AV septal defect have undergone surgical repair in infancy. Such infants have dyspnea, congestive heart failure, and failure to thrive. When initially seen unrepaired, most adults have established pulmonary vascular disease. Patients with Down syndrome have a propensity for the development of pulmonary hypertension at an even earlier age than do other patients with AV septal defects.

Clinical Issues

DOWN SYNDROME. Down syndrome occurs in 35% of patients with AV septal defects. These patients more commonly have a complete AV septal defect with a common AV valve orifice and a large associated VSD. They are often seen in infancy with pulmonary hypertension. Clinical features include cardiomegaly, a right ventricular heave, and a pulmonary outflow tract murmur. If associated AV valve regurgitation exists, a pansystolic murmur is present.

NON-DOWN SYNDROME. The clinical features depend on the presence and size of the ASD and the VSD and on the competence of the left AV valve. A large left-to-right shunt gives rise to symptoms of heart failure (exertional dyspnea or fatigue) or pulmonary vascular disease (exertional syncope, cyanosis). In adulthood, palpitations from atrial arrhythmias are common. Cardiac findings on physical examination of patients with an isolated shunt at the atrial level are similar to those of patients with secundum ASD, with the important

addition of a prominent left ventricular apex and pansystolic murmur when significant left AV valve regurgitation is present. Patients with a primum ASD and a restrictive VSD have similar findings, but with the addition of a pansystolic VSD murmur heard best at the left sternal border. Complete AV septal defects have a single S_1 (common AV valve), a mid-diastolic murmur from augmented AV valve inflow, and findings of pulmonary hypertension and/or a right-to-left shunt.

Laboratory Investigations

Electrocardiography. Most patients have left-axis deviation. Complete AV block and/or atrial fibrillation or flutter can be present in older patients. Partial or complete right bundle branch block is usually associated with right ventricular dilation or previous surgery.

Chest Radiography. In unrepaired patients, chest radiography demonstrates cardiomegaly with right atrial and right ventricular prominence and increased pulmonary vascular markings. Those with a small interatrial communication and important left AV valve regurgitation have cardiomegaly because of left ventricular enlargement and normal pulmonary vascular markings. Findings of Eisenmenger syndrome are also possible. When repaired, the heart and lungs may appear normal.

Echocardiography. This has replaced angiography in assessing virtually all patients with AV septal defects. The cardinal and common features discussed in the morphology section are readily recognized with echocardiography. In the four-chamber view the AV valve or valves appear at the same level, irrespective of the presence or absence of a VSD. The typical inferior ASD and a posteriorly positioned VSD will be sought. The degree of associated AV valve regurgitation, the left-to-right shunt, and the estimated right ventricular systolic pressure should be determined. When using the right AV valve to assess right ventricular pressure, care must be taken to ensure that the jet is not contaminated by an obligatory left ventricular-to-right atrial shunt. Three-dimensional echocardiography may also be useful in planning surgical interventions because it increases our understanding of this complex anatomy.⁴⁰

Cardiac Catheterization. In general this technique has been replaced by echocardiography for the evaluation of patients with an

AV septal defect. The one role that it still has is for the evaluation of a patient who is initially seen late in the course and may have associated pulmonary vascular or coronary disease.

Indications for Intervention

Patients with an unoperated or newly diagnosed AV septal defect and significant hemodynamic defects require surgical repair. Equally, patients with persistent left AV valve regurgitation (or stenosis from previous repair) causing symptoms, atrial arrhythmia, or deterioration in ventricular function or patients with significant subaortic obstruction (mean gradient >50 mm Hg at rest) require surgical intervention.

In the presence of severe pulmonary hypertension (pulmonary artery pressure > $\frac{1}{3}$ systemic blood pressure or pulmonary arteriolar resistance > $\frac{1}{3}$ systemic arteriolar resistance), there must be a net left-to-right shunt of at least 1.5:1 or evidence of pulmonary artery reactivity when challenged with a pulmonary vasodilator (e.g., oxygen, nitric oxide, and/or prostaglandins).

Interventional Options and Outcomes

ISOLATED SHUNT AT THE ATRIAL LEVEL (PRIMUM ATRIAL SEPTAL DEFECT). Pericardial patch closure of a primum ASD with concomitant suture (with or without annuloplasty) of the “cleft” left AV valve is usually performed. When left AV valve repair is not possible, replacement may be necessary. In the short term the results of repair of partial AV septal defects are similar to those following closure of secundum ASDs, but the sequelae of left AV (“mitral”) valve regurgitation, subaortic stenosis, and AV block may develop or progress.

COMPLETE ATRIOVENTRICULAR SEPTAL DEFECT. The “staged approach” (pulmonary artery banding followed by intracardiac repair) has been supplanted by primary intracardiac repair in infancy. The goals of intracardiac repair are ventricular and atrial septation with adequate left and right AV valve reconstruction. Single-, double-, and no-patch techniques to close ASDs and VSDs have been described with comparable results. Occasionally, left AV valve replacement is necessary when valve repair is not possible. The intermediate results of repair of complete AV septal defects are good in patients with Down syndrome, as well as in those without Down syndrome, with similar problems as with partial AV septal defects.

Reproductive Issues

Pregnancy is well tolerated in patients with complete repair and no significant residual lesions. Women in NYHA Classes I and II with unoperated, isolated primum ASDs usually tolerate pregnancy well. Pregnancy is contraindicated in those with Eisenmenger syndrome because of the high maternal ($\approx 50\%$) and fetal ($\approx 60\%$) mortality.

Follow-Up Issues

All patients who undergo repair require periodic follow-up by an expert cardiologist because the 5-year freedom from reoperation is only 74%.⁴¹ Long-term complications include patch dehiscence or residual septal defects (1%), development of complete heart block (3%), late atrial fibrillation or flutter, significant left AV valve dysfunction (10%), and subaortic stenosis (5% to 10%). Left AV valve regurgitation requiring left AV valve repair or replacement occurs in least 10% to 20% of patients.^{42,43} Subaortic stenosis develops or progresses in 5% to 10% of

patients after repair, particularly in those with primum ASDs, especially if the left AV (“mitral”) valve has been replaced. Particular attention should be paid to patients with pulmonary hypertension preoperatively. Antibiotic prophylaxis is necessary only in the first 6 months following surgery unless a residual patch leak or a prosthetic valve is present.

Isolated Ventricular Septal Defect

Morphology. The ventricular septum can be divided into three major components—inlet, trabecular, and outlet—all abutting on a small membranous septum lying just underneath the aortic valve. VSDs are classified into three main categories according to their location and margins (**Figs. 62-19 and 62-20**). *Muscular* VSDs are bordered entirely by myocardium and can be trabecular, inlet, or outlet in location. *Membranous* VSDs often exhibit inlet, outlet, or trabecular extension and are bordered in part by fibrous continuity between the leaflets of an AV valve and an arterial valve. *Doubly committed* subarterial VSDs are more common in Asian and South American patients, are situated in the outlet septum, and are bordered by fibrous continuity of the aortic and pulmonary valves (Videos 62-42 through 62-44). This section deals with VSDs occurring in isolation from major associated cardiac anomalies.

Pathophysiology. A *restrictive* VSD is a defect that produces a significant pressure gradient between the left ventricle and the right ventricle (pulmonary-aortic systolic pressure ratio <0.3) and is accompanied by a small ($\leq 1.4:1$) shunt. A *moderately restrictive* VSD is accompanied by a moderate shunt (Q_p/Q_s of 1.4 to 2.2) with a pulmonary-aortic systolic pressure ratio less than 0.66. A large or *nonrestrictive* VSD is accompanied by a large shunt ($Q_p/Q_s > 2.2$) and a pulmonary-aortic systolic pressure ratio greater than 0.66. An *Eisenmenger* VSD has a systolic pressure ratio of 1 and a Q_p/Q_s of less than 1:1, or a net right-to-left shunt.

Natural History

A *restrictive* VSD does not cause significant hemodynamic derangement and may close spontaneously during childhood and sometimes in adult life. A perimembranous defect in an immediately subaortic position—or any doubly committed VSD—may be associated with progressive aortic regurgitation. Late development of subaortic and

FIGURE 62-19 Montage of the different types of VSDs. The **center** diagram outlines the location of the various types of defects as seen from the right ventricle. The two **left** images show a perimembranous VSD as seen on the five-chamber and short-axis views. Note that the defect is roofed by the aorta and is next to the tricuspid valve. The **bottom middle** echocardiogram shows a muscular apical defect. The **upper right** image is a right anterior oblique view of a doubly committed VSD. The **lower right** is a short-axis view showing an outlet VSD with prolapse of the right coronary cusp. AO = aorta; LV = left ventricle; PA = pulmonary artery; RA = right atrium; RV = right ventricle.

**VIDEO 62-42**

Doubly committed subarterial VSD. This short-axis image shows a doubly committed VSD with the dilated right coronary cusp bulging into it. Note that the aortic and pulmonary valves hinge at the same level because of absence of the infundibular septum.

VIDEO 62-43

Doubly committed subarterial VSD. This short-axis image shows prolapse of the right coronary cusp, which is almost completely occluding a large doubly committed subarterial VSD. Note that the defect does not extend back to the tricuspid valve.

VIDEO 62-44

Doubly committed subarterial VSD. This long-axis view shows the right coronary cusp prolapsed into the doubly committed subarterial VSD.

FIGURE 62-20 The four components of the ventricular septum shown here from the right ventricular aspect are now described by Anderson and associates as inlet and outlet components of the right ventricle because these areas do not correspond to septal structures as initially suggested. Ao = aorta; PT = pulmonary trunk. (Modified from Anderson RH, Becker AE, Lucchese E, et al: *Morphology of Congenital Heart Disease*. Baltimore, University Park Press, 1983.)

subpulmonary stenosis (see the section on double-chambered right ventricle), as well as the formation of a left ventricular-to-right atrial shunt, is well described and should be excluded at follow-up. A *moderately restrictive* VSD imposes a hemodynamic burden on the left ventricle, which leads to left atrial and ventricular dilation and dysfunction, as well as to a variable increase in pulmonary vascular resistance. A large or nonrestrictive VSD, in the absence of obstruction to pulmonary blood flow, features left ventricular volume overload early in life with a progressive rise in pulmonary artery pressure and a fall in left-to-right shunting. In turn, this leads to higher pulmonary vascular resistance and eventually to Eisenmenger syndrome.

Clinical Features

Similar to ASD and AV septal defect, most patients with significant defects undergo closure in childhood. Large VSDs will usually produce symptoms in early infancy, and closure at 3 to 6 months of age is the norm. The role of “prophylactic” VSD closure in children with a substrate for the development of aortic incompetence is controversial, with most units waiting for mild aortic incompetence to develop before advising surgery (which generally reverses or stabilizes its progression). Most adult patients with a small *restrictive* VSD are asymptomatic. Physical examination reveals a harsh or high-frequency pansystolic murmur, usually grade 3 to 4/6 and heard with maximal intensity at the left sternal border in the third or fourth intercostal space. Patients with a *moderately restrictive* VSD often have dyspnea in adult life, perhaps triggered by atrial fibrillation. Physical examination typically reveals a displaced cardiac apex with a similar pansystolic murmur, as well as an apical diastolic rumble and third heart sound at the apex as a result of increased flow through the mitral valve. Patients with large *nonrestrictive* Eisenmenger VSDs are initially seen as adults with central cyanosis and clubbing of the nail beds. Signs of pulmonary hypertension—right ventricular heave, palpable and loud P₂, and a right-sided S₄—are typically present. A pulmonary ejection click, a soft and scratchy systolic ejection murmur, and a high-pitched decrescendo diastolic murmur of pulmonary regurgitation (Graham Steell) may be audible. Peripheral edema usually reflects right-sided heart failure.

Laboratory Investigations

Electrocardiography. The ECG mirrors the size of the shunt and the degree of pulmonary hypertension. Small, *restrictive* VSDs usually produce a normal tracing. *Moderate*-sized VSDs produce a broad, notched P wave characteristic of left atrial overload, as well as evidence of left ventricular volume overload, namely, deep Q and tall R waves with tall T waves in leads V₅ and V₆, and perhaps eventually atrial fibrillation. Following repair of perimembranous defects, a right bundle branch block is usually present.

Chest Radiography. The chest radiograph reflects the magnitude of the shunt, as well as the degree of pulmonary hypertension. A *moderate*-sized shunt causes signs of left ventricular dilation with some pulmonary plethora.

Echocardiography. Transthoracic echocardiography can be used to identify the location, size, and hemodynamic consequences of the VSD, in addition to any associated lesions (aortic regurgitation, right ventricular outflow tract obstruction, or left ventricular outflow tract obstruction) (Videos 62-45 through 62-51).

Cardiac Catheterization. Cardiac catheterization may be required when the hemodynamic significance of a VSD is questioned or when assessment of pulmonary artery pressure and resistance is necessary. In some centers, therapeutic catheterization is performed for percutaneous closure (see later).

Indications for Intervention

The presence of a significant VSD (symptoms, significantly increased left ventricular and left atrial size, or deteriorating left ventricular function) in the absence of irreversible pulmonary hypertension warrants surgical closure. If severe pulmonary hypertension (see the ASD section) is present, closure is seldom feasible. Other relative indications for VSD closure include the presence of a perimembranous or outlet VSD with more than mild aortic regurgitation and patients with a history of recurrent endocarditis.

Interventional Options and Outcomes

SURGERY. Surgical closure by direct suture or with a patch has been performed for more than 50 years with low perioperative mortality—even in adults—and a high closure rate. Patch leaks are not uncommon but seldom need reoperation. Late sinus node disease may occur.

DEVICE CLOSURE. Successful transcatheter device closure of trabecular (muscular) and perimembranous VSDs has been reported. Trabecular VSDs have proved more amenable to this technique because of their relatively straightforward anatomy and a muscular rim to which the device attaches well and therefore results in excellent closure rates with low procedural mortality. Immediate- and short-term results are good. Closure of perimembranous VSDs is technically more challenging because of their proximity to valve structures; careful patient selection is required. It has not gained widespread acceptance and should be performed only in centers with appropriate expertise. Short-term follow-up data show complete closure in 96% of patients and the development of aortic and/or tricuspid regurgitation and complete heart block in less than 15% of patients. The device is not approved for use in the United States. No long-term follow-up data are yet available from elsewhere.

Reproductive Issues

Pregnancy is well tolerated in women with small or moderate VSDs and in those with repaired VSDs. Pregnancy is contraindicated in women with Eisenmenger syndrome because of high maternal (≈50%) and fetal (≈60%) mortality.

Follow-Up

In patients with a good to excellent functional class and good left ventricular function before surgical closure, life expectancy after surgical correction is close to normal. The risk for progressive aortic regurgitation is reduced after surgery, as is the risk for endocarditis, unless a residual VSD persists. Yearly cardiac evaluation is suggested for patients with right ventricular outflow tract obstruction, left ventricular outflow tract obstruction, and aortic regurgitation not undergoing surgical repair; patients with Eisenmenger syndrome; and adults with significant atrial or ventricular arrhythmias. Cardiac

VIDEO 62-50

Perimembranous VSD with right ventricular muscle bundles and a small subaortic ridge. This loop shows the right ventricular muscle bundles in a patient with a perimembranous VSD. Note that the muscle bundles sit at the “OS” infundibulum, which is above the VSD.

VIDEO 62-51

Perimembranous VSD with right ventricular muscle bundles and a small subaortic ridge. This loop shows the VSD and the right ventricular muscle bundles as documented by color Doppler.

surveillance is also recommended for patients who undergone late repair of moderate or large defects, which are often associated with left ventricular impairment and elevated pulmonary artery pressure at the time of surgery.

Patent Ductus Arteriosus

Morphology. The ductus arteriosus is derived from the left sixth primitive aortic arch and connects the proximal left pulmonary artery to the descending aorta, just distal to the left subclavian artery.

Pathophysiology. The ductus is widely patent in a normal fetus and carries unoxygenated blood from the right ventricle through the descending aorta to the placenta, where the blood is oxygenated. Functional closure of the ductus as a result of vasoconstriction occurs shortly after a term birth, whereas anatomic closure as a result of intimal proliferation and fibrosis takes several weeks to complete. Some patients have “ductus-dependent” physiology as neonates, which means that their circulation depends on the ductus for pulmonary blood flow, such as in those with severe aortic coarctation, hypoplastic left heart syndrome, and sometimes D-TGA. If spontaneous closure of the ductus occurs in such neonates, clinical deterioration and death usually follow.

Isolated PDAs, the subject of this section, are often categorized according to the degree of left-to-right shunting, which is determined by both the size and length of the duct and the difference between systemic and pulmonary vascular resistance, as follows:

- Silent: tiny PDA detected only by nondiagnostic means (usually echocardiography)
- Small: continuous murmur common; $Q_p/Q_s < 1.5$
- Moderate: continuous murmur common; Q_p/Q_s 1.5 to 2.2
- Large: continuous murmur present; $Q_p/Q_s > 2.2$
- Eisenmenger: continuous murmur absent; substantial pulmonary hypertension, differential hypoxemia, and differential cyanosis (pink fingers, blue toes)

Clinical Features

A *small* audible duct usually causes no symptoms but may rarely be a manifestation of an endovascular infection. Physical examination may reveal a grade 1 or 2 continuous murmur peaking in late systole and best heard in the first or second left intercostal space. Patients with a *moderate*-sized duct may have dyspnea or palpitations from atrial arrhythmias. A louder continuous or “machinery” murmur in the first or second left intercostal space is typically accompanied by wide systemic pulse pressure from aortic diastolic runoff into the pulmonary trunk and signs of left ventricular volume overload, such as a displaced left ventricular apex and sometimes a left-sided S_3 (meaningful in adults only). With a moderate degree of pulmonary hypertension, the diastolic component of the murmur disappears, with a systolic murmur being left. Adults with a *large* uncorrected PDA eventually have a short systolic ejection murmur, hypoxemia in the feet more than in the hands (differential cyanosis), and Eisenmenger physiology.

Laboratory Investigations

Electrocardiography. The ECG reflects the size and degree of shunting occurring through the duct. A *small* duct produces normal findings on the ECG. A *moderate* duct may show left ventricular volume overload with broad, notched P waves together with deep Q waves, tall R waves, and peaked T waves in V_5 and V_6 . A *large* duct with Eisenmenger physiology produces findings of right ventricular hypertrophy.

Chest Radiography. A *small* duct produces normal findings on a chest radiograph. A *moderate*-sized duct causes moderate cardiomegaly with left-sided heart enlargement, a prominent aortic knuckle, and increased pulmonary perfusion. Ring calcification of the ductus may be seen through the soft tissue density of the aortic arch or pulmonary trunk in older adults. A large PDA produces an Eisenmenger appearance with a prominent aortic knuckle.

Echocardiography. Echocardiography is used to determine the presence, size, and degree of shunting and the physiologic consequences of the shunt. A PDA is seen with difficulty in an Eisenmenger context. A bubble study shows the communication.

Indications for Intervention

There is no debate about the desirability of closing a hemodynamically important PDA with significant left-to-right shunting at any age. There is ongoing debate, however, about the merits of closing an

inaudible or small PDA strictly to reduce the risk for endarteritis.⁴⁴ In the presence of severe pulmonary hypertension (see the earlier section on ASD), closure is seldom indicated. Contraindications to ductal closure include irreversible pulmonary hypertension or active endarteritis.

Interventional Options and Outcomes

TRANSCATHETER TREATMENT (Fig. e62-1). Over the past 20 years the efficacy and safety of transcatheter device closure in patients with ducts smaller than 8 mm have been established, with complete ductal closure being achieved in more than 85% by 1 year following device placement at a mortality rate of less than 1%.⁴⁵ In centers with appropriate resources and experience, transcatheter device occlusion should be the method of choice for ductal closure.⁴⁶

SURGICAL TREATMENT. Surgical closure by ductal ligation and/or division has been performed for more than 50 years and has a marginally greater closure rate than device closure does but somewhat greater morbidity and mortality. Immediate clinical closure (no shunt audible on physical examination) is achieved in more than 95% of patients. Surgical closure is a low-risk procedure in children. Surgical mortality in adults is 1% to 3.5% and is related to the presence of pulmonary arterial hypertension and the difficult ductal morphology (calcified or aneurysmal) often seen in adults. Surgical closure should be reserved for those in whom the PDA is too large for device closure or at centers without access to device closure.

Reproductive Issues

Pregnancy is well tolerated in women with silent and small PDAs and in patients who were asymptomatic before pregnancy. In women with a hemodynamically important PDA, pregnancy may precipitate or worsen heart failure. Pregnancy is contraindicated in those with Eisenmenger syndrome because of the high maternal ($\approx 50\%$) and fetal ($\approx 60\%$) mortality.

Follow-Up

After device occlusion or surgical closure patients should be examined periodically for possible recanalization. Silent residual shunts may be found by transthoracic echocardiography. Endocarditis prophylaxis is recommended for 6 months following device closure of a PDA or for life if any residual defect persists. Patients with a silent or small PDA probably do not require endocarditis prophylaxis or follow-up.

Persistent Truncus Arteriosus

Morphology. Persistent truncus arteriosus is an anomaly in which a single vessel forms the outlet of both ventricles and gives rise to the systemic, pulmonary, and coronary arteries. It is always accompanied by a VSD and frequently by a right-sided aortic arch. The truncal valve is usually tricuspid but is quadricuspid in approximately a third of patients. Truncal valve regurgitation and truncal valve stenosis are each seen in 10% to 15% of patients. There can be a single coronary artery.

Truncus is classified anatomically according to the mode of origin of the pulmonary vessels from the common trunk. In the most common type (type I), a partially separate pulmonary trunk of variable length exists and gives rise to the left and right pulmonary arteries. In type II each pulmonary artery arises separately but close to the other from the posterior aspect of the truncus. In type III each pulmonary artery arises separately from the lateral aspect of the truncus. Less commonly, one pulmonary artery branch may be absent, with aortopulmonary collateral arteries supplying the lung that does not receive a pulmonary artery branch from the truncal artery.

Pathophysiology. Pulmonary blood flow is governed by the size of the pulmonary arteries and by pulmonary vascular resistance. In infancy, pulmonary blood flow is usually excessive because pulmonary vascular resistance is not greatly increased. Thus in neonates, only minimal cyanosis is present. With time, pulmonary vascular resistance increases, which relieves the left ventricular volume load but at the price of increasing cyanosis. When pulmonary vascular resistance reaches systemic levels, Eisenmenger physiology and bidirectional shunting occur. Significant truncal valve regurgitation produces a volume load on both the right and left ventricles because of the biventricular origin of the truncal artery.

FIGURE e62-1 Montage of a patent arterial duct (*arrow*) before and after device occlusion. AO = aorta; MPA = main pulmonary artery.

Natural History

Most deaths from congestive heart failure take place before 1 year of age. Unoperated patients who survive past 1 year will most likely have established pulmonary hypertension. The prevalence of truncal valve regurgitation increases with age and it causes biventricular heart failure and increasing susceptibility to endocarditis.

Clinical Features

Infants with truncus arteriosus generally have mild cyanosis coexisting with the cardiac findings of a large left-to-right shunt. This is the result of excessive pulmonary blood flow because of low pulmonary vascular resistance. Symptoms of heart failure and poor physical development generally appear in the first weeks or months of life. The most frequent physical findings include cardiomegaly, collapsing peripheral pulses, a loud single second heart sound, a harsh systolic murmur preceded by an ejection click, and a low-pitched mid-diastolic rumbling murmur and bounding pulses. A decrescendo diastolic murmur suggests associated truncal valve regurgitation.

DiGeorge syndrome may be seen with truncus arteriosus. Facial dysmorphism, a high incidence of extracardiac malformations (particularly of the limbs, kidneys, and intestine), atrophy or absence of the thymus gland, T lymphocyte deficiency, and a predilection to infection may also be features.

The physical findings are different if pulmonary blood flow is restricted by high pulmonary vascular resistance: cyanosis is prominent, and only a short systolic murmur may be heard in association with an ejection click. Pulmonary vascular obstruction does not usually restrict pulmonary blood flow before 1 year of age.

Adults with an unrepaired truncus arteriosus can be expected to have Eisenmenger syndrome and its typical findings.

Laboratory Investigations (Unrepaired)

Electrocardiography. The ECG demonstrates biventricular hypertrophy with strain as pulmonary resistance rises.

Chest Radiography. This demonstrates cardiomegaly with prominent pulmonary arterial markings and unusually high hilar areas. A right aortic arch occurs in 50% of cases.

Echocardiography (Fig. e62-2). In most cases, two-dimensional echocardiography provides a complete diagnosis. The study should demonstrate the overriding truncal root, the origin of the pulmonary arteries, the number of truncal cusps, the origin of the coronary arteries, the functional status of the truncal valve, and VSD size.

Cardiac Catheterization and Angiography. This is rarely necessary and in fact carries a risk for both morbidity and mortality. In general, significant arterial desaturation in the absence of branch pulmonary artery stenosis indicates that the lesion cannot be repaired.

Indications for Intervention

Early surgical intervention—within the first 2 months of life—is indicated in all cases. In the presence of severe pulmonary hypertension (see the section on ASD), surgical intervention is not generally performed.

Interventional Options and Outcomes

Surgery consists of closure of the VSD, with the aorta arising from the left ventricle; excision of the pulmonary arteries from their truncus origin; and placement of a valve-containing prosthetic conduit or aortic homograft valve conduit between the right ventricle and the pulmonary arteries to establish circulatory continuity. Truncal valve insufficiency is a challenging problem and may require valve replacement or repair.

Important risk factors for perioperative death are severe truncal valve regurgitation, interrupted aortic arch, coronary artery anomalies, and age at initial operation older than 100 days. Patients with only one pulmonary artery are especially prone to the early development of severe pulmonary vascular disease.

Reproductive Issues

Patients with a repaired truncus arteriosus and no hemodynamically important residual lesions should tolerate pregnancy well. Those with significant conduit obstruction and/or important truncal valve regurgitation need prepregnancy counseling, with consideration of

correction of the lesions before pregnancy and/or careful follow-up throughout pregnancy. Pregnancy is contraindicated in patients with Eisenmenger syndrome given its 50% maternal mortality.

Follow-Up

Patients operated on early (<1 year of age) generally do well. However, conduit change is often indicated within the first few years after repair as the patient outgrows its size. Patients with significant truncal valve stenosis and/or regurgitation may eventually require truncal valve replacement. Patients operated on late (>1 year of age) require careful follow-up for any signs of progression of pulmonary hypertension. Endocarditis prophylaxis is essential in all patients.

Cyanotic Heart Disease

Tetralogy of Fallot (Including Tetralogy with Pulmonary Atresia)

Morphology (Figs. 62-21 and 62-22). The four components of tetralogy of Fallot are an outlet VSD, obstruction to right ventricular outflow, overriding of the aorta (>50%), and right ventricular hypertrophy. The fundamental abnormality contributing to each of these features is anterior and cephalad deviation of the outlet septum, which is malaligned with respect to the trabecular septum. Thus tetralogy may occur in the setting of a double-outlet right ventricle (aortic override >50%) and may coexist with an AV septal defect. Right ventricular outflow tract obstruction is variable. Frequently, a stenotic, bicuspid pulmonary valve with supravalvular hypoplasia exists. The dominant site of obstruction is usually at the subvalve level. In some cases the outflow tract is atretic and the heart can be diagnosed as having tetralogy of Fallot with pulmonary atresia (also known as *complex pulmonary atresia* when major aortopulmonary collateral arteries are present). The management and outcome of patients with major aortopulmonary collateral arteries differ significantly from that in patients with less extreme forms of the tetralogy and are discussed separately at the end of this section.

Associated Anomalies. A right aortic arch is seen in approximately 25% of patients, and abnormalities of the course of the coronary arteries occur in approximately 5%. In the most common anomaly the anterior descending artery originates from the right coronary artery and courses anteriorly to cross the infundibulum of the right ventricle. Furthermore, the origin of the left main bronchus is often

FIGURE 62-21 Diagrammatic representation of tetralogy of Fallot. 1, Pulmonary stenosis; 2, VSD; 3, overriding aorta; 4, right ventricular hypertrophy. Ao = aorta; LA = left atrium; LV = left ventricle; PA = pulmonary artery; RA = right atrium; RV = right ventricle. (From Mullins CE, Mayer DC: *Congenital Heart Disease: A Diagrammatic Atlas*. New York, Wiley-Liss, 1988.)

FIGURE e62-2 View of the origin of the pulmonary artery in truncus arteriosus. Note the lateral origin of the pulmonary artery. AT = ascending trunk; PA = pulmonary artery; V = ventricle.

FIGURE 62-22 Diagrammatic representation of surgical repair of tetralogy of Fallot. 1, Patch closure of a VSD; 2, right ventricular outflow/main pulmonary artery outflow patch (transannular patch). Ao = aorta; LA = left atrium; LV = left ventricle; PA = pulmonary artery; RA = right atrium; RV = right ventricle. (From Mullins CE, Mayer DC: *Congenital Heart Disease: A Diagrammatic Atlas*. New York, Wiley-Liss, 1988.)

rotated clockwise, which increases the risk for coronary compression during later right ventricular outflow tract stenting or stent-valve placement. Absent pulmonary valve syndrome is a rare form of the tetralogy in which stenosis and regurgitation of the right ventricular outflow tract are due to a markedly stenotic pulmonary valve ring with poorly formed or absent valve leaflets. The pulmonary arteries are usually markedly dilated or aneurysmal and may produce airway compression at birth, a poor prognostic feature.

Pathophysiology. In the absence of alternative sources of pulmonary blood flow, the degree of cyanosis reflects the severity of right ventricular outflow tract obstruction and the level of systemic vascular resistance. There is right-to-left shunting across the VSD. A tetralogy “spell” is an acute fall in arterial saturation, and it may be life-threatening. Its treatment is aimed at relieving obstruction and increasing systemic resistance. Relief of hypoxia with oxygen and morphine, intravenous propranolol, and systemic vasoconstriction (e.g., squatting, knee-chest position, vasoconstrictor drugs) generally reverses the cyanosis.

Natural History

Progressive hypoxemia in the first years of life is expected. Survival to adult life is rare without palliation or correction. The presence of additional sources of blood supply (see later) modifies the rate of progression of cyanosis and its complications.

Clinical Features

UNOPERATED PATIENTS. Variable cyanosis exists. A right ventricular impulse and systolic thrill are often palpable along the left sternal border. An early systolic ejection sound that is aortic in origin may be heard at the lower left sternal border and apex; the second heart sound is usually single. The intensity and duration of the systolic ejection murmur vary inversely with the severity of subvalve obstruction—the opposite of the relationship that exists in patients with pulmonary valve stenosis. With extreme outflow tract stenosis or pulmonary atresia and during an attack of paroxysmal hypoxemia, no murmur or only a short, faint murmur may be detected. A continuous murmur faintly audible over the anterior or posterior aspect of the chest reflects flow through aortopulmonary collateral vessels or a duct.

AFTER PALLIATIVE SURGERY. Progressive cyanosis with its complications can result from worsening right ventricular outflow tract obstruction, gradual stenosis and occlusion of palliative aortopulmonary shunts, or the development of pulmonary hypertension (sometimes seen after Waterston or Potts shunts). Progressive ascending aortic dilation and aortic regurgitation can occur. Central cyanosis and clubbing are invariably present.

AFTER REPARATIVE SURGERY. After intracardiac repair, more than 85% of patients are asymptomatic on follow-up, although objective testing will generally demonstrate a reduction in maximal exercise performance. Palpitations from atrial and ventricular arrhythmias and exertional dyspnea from progressive right ventricular dilation secondary to chronic pulmonary regurgitation or severe residual right ventricular outflow tract obstruction occur in 10% to 15% of patients within 20 years after initial repair. An ascending aortic aneurysm and significant aortic regurgitation from a dilated aortic root may also be present. A parasternal right ventricular lift and a soft and delayed or absent P₂ with a low-pitched diastolic murmur from pulmonary regurgitation may be present. A systolic ejection murmur from right ventricular outflow tract obstruction, a high-pitched diastolic murmur from aortic regurgitation, and a pansystolic murmur from a VSD patch leak may also be heard.

TETRALOGY OF FALLOT WITH PULMONARY ATRESIA AND MAJOR AORTOPULMONARY COLLATERAL ARTERIES. This subgroup represents one of the greatest challenges in managing CHD. The aim of unifocalization surgery is to amalgamate all the sources of pulmonary blood flow and establish unobstructed right ventricle-to-pulmonary artery continuity while achieving normal pulmonary artery pressure and a closed ventricular septum. When this is not possible, a combined interventional catheterization and surgical approach may be indicated. Balloon dilation and stenting of stenosed arteries and anastomoses can “rehabilitate” the segmental supply and allow subsequent VSD closure or, if already closed, reduce right ventricular pressure (Video 62-52).

Laboratory Investigations

Electrocardiography. Right-axis deviation with right ventricular and right atrial hypertrophy is common. In adults with repaired tetralogy of Fallot, a complete right bundle branch block following repair has been the rule. QRS width may reflect the degree of right ventricular dilation and, when extreme (>180 milliseconds) or rapidly progressive, may be a risk factor for sustained ventricular tachycardia and sudden death.

Chest Radiography. Characteristically, an unrepaired patient has a normal-sized, boot-shaped heart (*coeur en sabot*) with prominence of the right ventricle and a concavity in the region of the underdeveloped right ventricular outflow tract and main pulmonary artery. Pulmonary vascular markings are typically diminished, and the aortic arch may be on the right side (25%). The ascending aorta is often prominent. After repair, the right ventricle is frequently prominent, and the left heart border tends to be straightened by a dilated right ventricular outflow tract.

Echocardiography (Fig. 62-23). A complete diagnosis can usually be established by Doppler echocardiography alone. The study should identify the malaligned and nonrestrictive VSD and overriding aorta (<50% override), as well as the presence and degree of right ventricular outflow tract obstruction (infundibular, valvular, and/or pulmonary arterial stenosis). Cardiac catheterization is now rarely required before corrective surgery. The exception to this rule is when additional sources of pulmonary blood flow are present. In patients with repaired tetralogy of Fallot, residual pulmonary stenosis and regurgitation, residual VSD, right and left ventricular size and function, aortic root size, and the degree of aortic regurgitation should be assessed.

Cardiac Catheterization and Angiocardiology. Although echocardiography, MRA, and fast CT may delineate the presence and proximal course of the pulmonary blood vessels, preoperative assessment of the tetralogy and pulmonary atresia with major aortopulmonary collateral arteries usually includes delineation of the arterial supply to both lungs by selective catheterization and angiography to show the course and segmental supply from the collateral arteries and central pulmonary arteries. Major aortopulmonary collateral arteries generally arise from the descending aorta at the level of the tracheal bifurcation.

**VIDEO 62-52**

FIGURE 62-23 Montage of tetralogy of Fallot. The two **left** images are in the right anterior oblique view, which demonstrates the anteriorly deviated infundibular septum (*asterisk*) and the VSD. The *arrow* on the specimen points to the hypertrophied septoparietal trabeculations. The **right** images demonstrate the over-riding aorta and the VSD. AO = aorta; IS = infundibular septum; LA = left atrium; LV = left ventricle; PA = pulmonary artery; RA = right atrium; RV = right ventricle.

Magnetic Resonance Imaging. The goals of MRI examination after repair of tetralogy of Fallot include quantitative assessment of left and, particularly, right ventricular volumes, stroke volumes, and ejection fraction; imaging of the anatomy of the right ventricular outflow tract (Fig. e62-3), pulmonary arteries, aorta, and aortopulmonary collaterals; and quantification of pulmonary, aortic, and tricuspid regurgitation.

Indications for Intervention

CHILDREN. Symptomatic infants now undergo repair at any age, and elective repair in asymptomatic infants during the first 6 months is advocated by many. This is often at the expense of transannular patch enlargement of the right ventricular outflow tract, which is a risk factor for later reintervention. Marked hypoplasia of the pulmonary arteries, small body size, and prematurity are relative contraindications to early corrective surgery, and these patients may be palliated successfully by balloon dilation of the right ventricular outflow tract (with or without stenting) and pulmonary arteries (Video 62-53).

ADULTS, UNOPERATED. For unoperated adults, surgical repair is still recommended because the results are gratifying and the operative risk is comparable to that in pediatric series, provided that no serious coexisting morbidity is present.

PALLIATED. Palliation was seldom intended as a permanent treatment strategy, and most of these patients should undergo surgical repair. In particular, palliated patients with increasing cyanosis and erythrocytosis (from gradual shunt stenosis or the development of pulmonary hypertension), left ventricular dilation, or aneurysm formation in the shunt should undergo intracardiac repair with take-down of the shunt unless irreversible pulmonary hypertension has developed.

REPAIRED. The following situations *may* warrant intervention after repair: a residual VSD with a shunt greater than 1.5:1; residual pulmonary stenosis (either the native right ventricular outflow tract or valved conduit if one is present) with right ventricular systolic pressure two thirds or more of systemic pressure; or severe pulmonary regurgitation associated with substantial right ventricular dilation or dysfunction (i.e., right ventricular diastolic volume index >150 to 170 mL/m² or a right ventricular ejection fraction <45%),⁴⁷⁻⁴⁹

exercise intolerance, or sustained arrhythmias. The coexistence of substantial left ventricular dysfunction or a QRS duration longer than 180 milliseconds offers additional support when other indications are present. The development of major cardiac arrhythmias increases over time, most commonly atrial flutter or fibrillation (present in up to 20% of patients) or sustained ventricular tachycardia (present in up to 14% of patients).⁵⁰ The presence of arrhythmias usually reflects hemodynamic deterioration from the right and/or left side of the heart,⁵⁰ and they should be treated accordingly. Surgery is occasionally necessary for significant aortic regurgitation associated with symptoms or progressive left ventricular dilation and for aortic root enlargement of 55 mm or greater.⁵¹ Rapid enlargement of a right ventricular outflow tract aneurysm needs surgical attention.

Interventional Options

SURGERY. Reparative surgery involves closing the VSD with a Dacron patch and relieving the right ventricular outflow tract obstruction. The latter may involve resection of infundibular muscle and insertion of a right ventricular outflow tract or transannular patch—a patch across the pulmonary valve annulus that disrupts the integrity of the pulmonary valve and causes important pulmonary regurgitation.

When an anomalous coronary artery crosses the right ventricular outflow tract and precludes a patch, an extracardiac conduit is placed between the right ventricle and pulmonary artery to bypass the right ventricular outflow tract obstruction. A PFO or secundum ASD may be closed. Additional treatable lesions such as muscular VSDs, PDAs, and aortopulmonary collaterals should also be addressed at the time of surgery.

Reoperation is necessary in 10% to 15% of patients after reparative surgery over a 20-year follow-up. For persistent right ventricular outflow tract obstruction, resection of residual infundibular stenosis or placement of a right ventricular outflow or transannular patch, with or without pulmonary arterioplasty, can be performed. Occasionally, an extracardiac valved conduit may be necessary. Pulmonary valve replacement (either a homograft or xenograft) is used to treat severe pulmonary regurgitation. Concomitant tricuspid valve annuloplasty may be performed for moderate or severe tricuspid regurgitation. Concomitant cryoablation may be performed at the time of surgery for patients with either preexisting atrial or ventricular arrhythmias.

TRANSCATHETER. Percutaneous pulmonary valve replacement (Videos 62-54 and 62-55) can be performed with similar mortality and favorable hemodynamic short- and intermediate-term results with less morbidity than occurs with surgical pulmonary valve replacement but should be done only in adult CHD centers with expertise in the procedure. At present, these therapies are reserved primarily for patients with circumferential right ventricle–pulmonary artery conduits (i.e., homografts, valved conduits) measuring 22 mm or less, although transcatheter pulmonary valve replacement in native right ventricular outflow tracts has been performed.⁵² Significant branch pulmonary artery stenosis can be managed with balloon dilation and usually stent insertion.

IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR. Selection of appropriate candidates for primary prevention with implantable cardioverter-defibrillators (ICDs) remains controversial. ICDs are probably most beneficial in “high-risk patients” (e.g., previous palliative shunt, QRS >180 milliseconds, inducible ventricular tachycardia, and left ventricular dysfunction) and are perhaps best reserved for those with a high annual risk (≥3.5% per year) for sudden cardiac death. When a patient presents with ventricular tachycardia and no

FIGURE e62-3 MRI after repair of the tetralogy of Fallot demonstrating its usefulness in imaging right ventricular outflow tract aneurysms and in assessing right ventricular volumes. RV = right ventricle; RVOT = right ventricular outflow tract.

VIDEO 62-53

This neonate with pulmonary atresia and a VSD underwent radiofrequency-assisted balloon dilation of the atretic pulmonary valve. Because of recurrent outflow stenosis, a stent was placed in the outflow tract to further palliate the child until elective surgery was performed at 5 months of age.

VIDEO 62-54

In assessing for potential transcatheter pulmonary valve implantation, the coronary arteries must be distant from the conduit when fully expanded by the implant. In this sequence the left coronary artery is adherent to the posterior wall of the conduit and not a candidate for transcatheter valve implantation.

VIDEO 62-55

Conduit stenosis, seen in the first sequence of angiograms, developed in an adolescent. A percutaneous pulmonary valve (Melody, Medtronic Inc., Minneapolis) was implanted and resulted in resolution of the gradient and elimination of the pulmonary regurgitation.

underlying significant hemodynamic lesion, ICD implantation should be considered as a secondary prevention measure.⁵³

Interventional Outcomes

The overall survival of patients who have undergone initial operative repair is excellent, provided that the VSD has been closed and the right ventricular outflow tract obstruction has been relieved. A 25-year survival rate of 94% has been reported. Pulmonary valve replacement for chronic pulmonary regurgitation or right ventricular outflow tract obstruction after initial intracardiac repair can be done safely with a mortality rate of 2%.^{54,55} Pulmonary valve replacement, when performed for significant pulmonary regurgitation, leads to improvement in exercise tolerance, as well as favorable right ventricular remodeling.⁴⁹ Sudden death can occur. Ventricular tachycardia can originate at the site of the right ventriculotomy, from VSD patch sutures, or from the right ventricular outflow tract. Patients at high risk for sudden death include those with right ventricular dilation and a QRS duration of 180 milliseconds or longer on the ECG. Moderate to severe left ventricular dysfunction is another risk factor for sudden death.^{50,53,56} The reported incidence of sudden death is approximately 5%, which accounts for approximately a third of late deaths during the first 20 years of follow-up.

Reproductive Issues

Patients with repaired tetralogy of Fallot can undergo pregnancy relatively safely with an adverse cardiovascular event rate of between 8% and 17%.^{35,56}; adverse events consist mainly of arrhythmias and worsening NYHA class from right-sided heart failure.⁵⁷ Outcome of the offspring is related to maternal cardiovascular status before pregnancy, as well as cardiovascular events during pregnancy. Pregnant women with repaired tetralogy of Fallot should be monitored diligently during pregnancy.

Follow-Up

All patients should have expert cardiology follow-up every 1 to 2 years.

Fontan Procedure—Requiring Lesions. The next four sections describe lesions usually or often treated with a Fontan procedure, including tricuspid atresia, hypoplastic left heart syndrome, double-inlet ventricle, and isomerism. The *Fontan procedure* has become a generic term used to describe a palliative surgical procedure that redirects systemic venous return directly to the pulmonary arteries without passing through a subpulmonary ventricle. It is performed in patients with a “functionally single” ventricle or when biventricular intracardiac repair is not possible, even though two good-sized ventricles are present. Although undoubtedly imperfect, the Fontan circuit restores an in-series pulmonary-to-systemic circulation by removing the chronic volume load of the systemic ventricle previously supporting a parallel circuit of pulmonary and systemic circulations. The earliest iteration of the Fontan procedure was a simple “atriopulmonary” connection whereby the right atrium or its appendage was anastomosed to the pulmonary arteries. Because of the long-term problems of atrial dilation, arrhythmia, and thrombosis, this procedure has been abandoned in favor of hemodynamically superior versions. In the early 1990s the total cavopulmonary anastomosis or lateral-tunnel Fontan procedure was introduced. It consisted of a direct, end-to-side superior cavopulmonary anastomosis (bidirectional Glenn operation) in combination with an intra-atrial baffle or tube connection of the inferior vena cava to the underside of the confluent pulmonary arteries. More recently, the inferior vena cava has been directed to the pulmonary arteries via an extracardiac conduit, thereby completely excluding the atrium from the circuit. It remains to be seen whether these modifications will have the desired effect of reducing late morbidity, and all patients will require regular and careful review in special centers.

FIGURE 62-24 Apical four-chamber view of univentricular connection of the left ventricular type with absent right connection (tricuspid atresia). Note the wedge of sulcus tissue in the floor of the right atrium. LA = left atrium; LV = left ventricle; RA = right atrium; ST = sulcus tissue.

FIGURE 62-25 **A**, Tricuspid atresia with normally related great arteries, a small VSD, diminutive right ventricular chamber, and narrowed outflow tract. **B**, Example of tricuspid atresia and complete transposition of the great arteries in which the left ventricular chamber is essentially a common ventricle with the aorta arising from an infundibular component (RV) of the common ventricle. LA = left atrium; LPA = left pulmonary artery; LPV = left pulmonary vein; LV = left ventricle; PT = pulmonary trunk; RA = right atrium; RV = right ventricle; VC = vena cava. (Modified from Edwards JE, Burchell HB: Congenital tricuspid atresia: Classification. *Med Clin North Am* 33:1177, 1949.)

Tricuspid Atresia (Absent Right Atrioventricular Connection)

Morphology. *Classic tricuspid atresia* is best described as absence of the right AV connection (Figs. 62-24 and 62-25A, B, and see also Videos 62-22 and 62-23). Consequently an ASD must be present. There is usually hypoplasia of the morphologic right ventricle, which communicates with the dominant ventricle via a VSD. Patients may be subdivided into those with concordant ventriculoarterial connections and normally related great arteries (70% to 80% of cases) and those with discordant connections, in which the aorta arises from the small right ventricle and is fed via the VSD. Associated lesions in the latter group include subaortic stenosis and aortic arch anomalies.

Pathophysiology. The clinical picture and management are dominated by issues related to the ventriculoarterial connections. All patients have “mixing” of atrial blood, and thus their degree of cyanosis is governed by the amount of pulmonary blood flow and systemic venous saturation. Patients with concordant ventriculoarterial connections tend to be more cyanosed (depending on the size of the VSD), whereas those with discordant connections are pinker and heart failure tends to develop (because the unobstructed pulmonary circulation arises directly from the left ventricle). Some are associated with

a critical reduction in systemic blood flow because of obstruction at the VSD and/or associated aortic arch anomalies and behave much like hypoplastic left heart syndrome.

Laboratory Investigations

Electrocardiography. Left-axis deviation, right atrial enlargement, and left ventricular hypertrophy often occur. Left atrial enlargement may be present if pulmonary flow is high.

Chest Radiography. Situs solitus, levocardia, and a left-sided aortic arch usually occur. Heart size and pulmonary vascular markings vary with the amount of pulmonary blood flow. The main pulmonary trunk is inapparent. A right aortic arch exists in 25% of patients.

Echocardiography. This establishes the full segmental diagnosis. The size of the ASD, VSD, and aortic arch must all be carefully assessed.

Cardiac Catheterization. Catheterization is rarely required for initial diagnosis or management. It can be useful to assess the degree of subaortic stenosis (by evaluating the change in the left ventricle-to-aorta pressure gradient while performing an isoprenaline or dobutamine challenge) and is usually performed to measure pulmonary artery pressure and resistance before venopulmonary connections.

Management Options

In those with concordant ventriculoarterial connections and severe cyanosis, a systemic-to-pulmonary shunt is performed in the first 6 to 8 weeks of life, and in older children, a primary bidirectional Glenn procedure can be considered. In infants with discordant arterial connections, early palliation ranges from pulmonary artery banding to reduce pulmonary blood flow in those with no subaortic narrowing to a full Norwood stage 1 procedure in those with severe stenosis and a hypoplastic ascending aorta and arch.

The aim of early palliation is to prepare for a Fontan procedure, which should be performed only when there is good ventricular function, unobstructed systemic blood flow, and minimal AV valve regurgitation. Candidates for these corrective procedures must also have low pulmonary resistance, mean pulmonary artery pressure less than 15 mm Hg, and pulmonary arteries of adequate size.

Hypoplastic Left Heart Syndrome

Definition

Hypoplastic left heart syndrome is a generic term used to describe a group of closely related cardiac anomalies characterized by underdevelopment of the left cardiac chambers in association with atresia or stenosis of the aortic and/or mitral orifices and hypoplasia of the aorta. The term should be restricted to those with normally connected hearts and concordant AV and ventriculoarterial connections. Hypoplastic left heart syndrome (Fig. 62-26) is characterized by duct-dependent systemic blood flow and thus tends to be accompanied by severe symptoms within the first week of life as ductal constriction occurs. Untreated, the disease is almost uniformly fatal in infancy. In the past, many infants would have severe acidemic circulatory collapse, but this is becoming less frequent as fetal ultrasound screening for cardiac anomalies becomes more generally available and successful. Fetal diagnosis allows planned delivery and institution of prostaglandin therapy from birth and has now been proved to reduce subsequent preoperative morbidity and perioperative mortality during the first stage of surgical repair.

Pathophysiology. It remains uncertain whether hypoplastic left heart syndrome reflects a primary myocardial disease or is a consequence of a structural or hemodynamic abnormality. There is no doubt that in some patients an apparently isolated dilated cardiomyopathy in early fetal life may evolve (as a result of a subsequent lack of left ventricular growth) into hypoplastic left heart syndrome later in gestation. Congenital structural abnormalities clearly play a significant role as well. This is exemplified by the effect of isolated valvular stenosis in producing a continuum of hypoplastic left heart syndrome to critical aortic stenosis with a normal-sized left ventricle. Therefore hypoplastic left heart syndrome is probably multifactorial in origin.

Clinical Features

The diagnosis should be considered in any infant with a sudden onset of circulatory collapse and severe lactic acidosis. Thus it must be distinguished from neonatal sepsis and metabolic disorders. Until

FIGURE 62-26 Hypoplastic left heart syndrome with aortic hypoplasia, aortic valve atresia, and a hypoplastic mitral valve and left ventricle. AD = anterior descending; LC = left circumflex; LV = left ventricle; PA = pulmonary artery; PV = pulmonary vein; RA = right atrium; RC = right coronary artery; RV = right ventricle. (From Neufeld HN, Adams P Jr, Edwards JE, et al: *Diagnosis of aortic atresia by retrograde aortography*. *Circulation* 25:278, 1962.)

excluded, any child with this finding should be treated with prostaglandin, which may have a dramatically positive effect if there is an underlying cardiac abnormality and little effect if there is not.

Laboratory Investigations

Electrocardiography. The ECG frequently shows right-axis deviation, right atrial and ventricular enlargement, and ST and T wave abnormalities in the left precordial leads.

Chest Radiography. This usually shows some cardiac enlargement shortly after birth, but with clinical deterioration there may be marked cardiomegaly and increased pulmonary venous and arterial vascular markings.

Echocardiography (Fig. e62-4). Cross-sectional echocardiography provides a full segmental diagnosis. In its classic form the left ventricular cavity is small with a diminutive mitral valve. The myocardium may be thinned or be of normal thickness, but the endocardium is usually thickened, consistent with endocardial fibroelastosis. There may be fistulous communications between the left ventricular cavity and the coronary arteries, a feature much more likely when the mitral valve is patent rather than atretic. The aortic root is generally diminutive, less than 4 to 5 mm in diameter at the level of the sinuses of Valsalva and narrowed in its ascending portion. The aortic arch is usually larger, but juxtaductal coarctation is often present. The duct varies in size according to treatment, and assessment of this and the size of the interatrial communication is crucial for management. There may be profound desaturation and rapid demise (because of a combination of reduced pulmonary blood flow and pulmonary edema) in children with an intact atrial septum or restrictive PFO.

Management Options

Early treatment with prostaglandin is mandatory. Those initially seen while in shock require paralysis, mechanical ventilation, and inotropic support. Crucial to managing these patients is maintenance of

FIGURE e62-4 Long-axis view of the left ventricle (LV) and aorta (AO) in hypoplastic left heart syndrome. Note the associated endocardial fibroelastosis in the specimen.

balanced pulmonary and systemic blood flow. Cardiac output is fixed and is distributed according to the relative magnitude of systemic and pulmonary vascular resistance. Thus measures to elevate pulmonary resistance (by imposing hypercapnia or by alveolar hypoxia) and reduce systemic resistance (using vasodilators) are frequently required.

SURGICAL TREATMENT. Staged surgical management now provides long-term palliation to most patients with hypoplastic left heart syndrome. The first stage, often referred to as the *Norwood procedure*, now has many versions, but its essence is the creation of an unobstructed communication between the right ventricle and an unobstructed aorta. The right ventricular-to-aortic connection is accomplished by direct connection between the transected proximal pulmonary trunk and ascending aorta, usually with a patch extending around the augmented aortic arch. Pulmonary blood flow is established via a systemic-to-pulmonary shunt or the more recently introduced right ventricle-to-pulmonary artery conduit. The PDA is ligated, and a large interatrial communication is created. Early results of this procedure were poor, but survival rates higher than 85% have recently been published. Institutional variations, the interval mortality, and those unsuitable to progress to stage 2 must be taken into account, however, and in some centers the preferred operation is cardiac transplantation.

Stage 2 consists of an end-to-side superior vena cava-to-pulmonary artery connection (bidirectional Glenn procedure) or a hemi-Fontan (incorporating the roof of the atrium into the pulmonary artery anastomosis). This is performed at approximately 6 months of age as an intermediate step before stage 3, a Fontan operation. A newer innovation is the so-called hybrid procedure whereby at the first stage each pulmonary artery is banded separately and then to maintain ductal patency a stent is placed by the interventional cardiologist, either directly via the main pulmonary artery in concert with the surgeon or percutaneously. The second stage combines the surgical aortopulmonary anastomosis with the bidirectional Glenn procedure. It remains to be seen whether this approach confers a survival or physiologic advantage.

Adult Issues

Survivors of the early attempts at staged Norwood palliation are now entering adult life. Their issues are likely to be common to all late survivors of Fontan palliation with a systemic right ventricle.

Double-Inlet Ventricle

Definition

A double-inlet connection falls under the umbrella of univentricular AV connections. These hearts are defined as having more than 50% of each AV junction connected to a dominant ventricle. In practice this usually means that the whole of one and greater than 50% of the alternative junction are connected to either a left or a right ventricle. When a common junction is present, more than 75% of the junction must be connected to the dominant ventricle.

Morphology. In approximately 75% of patients the dominant ventricle is a left ventricle that is separated from the right ventricle by a VSD. In 20% the dominant ventricle is a right ventricle, and the small, incomplete ventricle is of left ventricular apical morphology. In only 5% of cases is there truly only one ventricle in the ventricular mass. With a double-inlet left ventricle the most common ventriculoarterial connection is discordant. Thus the aorta arises from the small right ventricle and is fed via the VSD, and the generally unobstructed pulmonary artery arises from the left ventricle. Aortic and aortic arch anomalies are frequent in these patients.

Pathophysiology. The basic circulatory physiology of a *double-inlet left ventricle* is identical to that of tricuspid atresia. Common

mixing of systemic and pulmonary venous blood occurs, and the blood is then ejected from the left ventricle into the pulmonary artery (with discordant connections) or into the aorta (with concordant connections). In the former the blood must pass through the VSD to gain egress to the aorta. Subaortic stenosis, aortic hypoplasia, and arch anomalies are therefore common. With a *double-inlet right ventricle*, patients with concordant ventriculoarterial connections are at particular risk for systemic outflow obstruction. One or both of the two AV valves (when present) may be stenotic, atretic, or regurgitant. In these circumstances the integrity of the atrial septum becomes important. If left or right atrial outflow obstruction is present, a septectomy or septostomy will be required.

Clinical Features

When systemic outflow is critically reduced, infants may be duct dependent and have acidemic shock. Conversely, when pulmonary blood flow is reduced, severe cyanosis or duct-dependent pulmonary blood flow may be present. Other patients may not be initially seen in the neonatal period and heart failure will develop because of increased pulmonary blood flow. Patients are managed with the same surgical algorithms as those with tricuspid atresia and therefore will ultimately undergo a Fontan operation. Their clinical issues are typical of any patient after this procedure.

Laboratory Investigations

Electrocardiography. Findings on the ECG are highly variable. Ventricular hypertrophy appropriate to the dominant ventricle is expected.

Chest Radiography. This is similarly variable and rarely diagnostic.

Echocardiography (Fig. 62-27, and see also Videos 62-11 through 62-13). A full segmental diagnosis should be possible in all patients. Particular attention should be paid to defining the AV valve anomalies and the presence and anatomy of any subaortic obstruction. This may develop, even if not present at birth, and should be part of the routine surveillance of these patients.

Indications and Options for Intervention

Survival without intervention may be prolonged, but at the expense of increasing cyanosis (when pulmonary blood flow is restricted) or pulmonary vascular disease (when pulmonary blood flow is not restricted). Those born with restricted systemic blood flow require urgent surgical intervention and usually undergo a Norwood-type repair to establish the pulmonary valve as the unobstructed systemic outflow tract. Pulmonary artery banding is offered only to infants with pulmonary overcirculation, heart failure, and unobstructed systemic outflow. Subsequently, and sometimes as the primary procedure, a bidirectional Glenn anastomosis is performed as a prelude to a Fontan procedure.

FIGURE 62-27 Apical four-chamber view of a double-inlet univentricular connection of the left ventricular type with two AV valves. LA = left atrium; LV = left ventricle; RA = right atrium.

Follow-Up

These patients should be reviewed frequently and in a center conversant with the issues of the Fontan operation.

Isomerism

Definition

For the purposes of illustrating the cardiac manifestations, isomerism describes the situation in which both atrial appendages have either left or right anatomic features (i.e., bilateral right or bilateral left atrial appendages).

Morphology. Experts have made many attempts to describe hearts with complex abnormalities in visceral and atrial situs whereby normal lateralization is lost. Terms such as *heterotaxy*, *asplenia*, and *polysplenia* fail to adequately describe either the visceral or cardiac manifestations with enough precision. The left atrial appendage is characterized by its tubular shape and pectinate muscles confined to the appendage. The pectinate muscles of the triangular right atrial appendage extend from its broad junction with the atrium to around the vestibule or AV junction. Thus the arrangement of the atria (be it usual, mirror image, right or left isomerism) can be defined independent of the venous anatomy.

In left isomerism it is not unusual to have a biventricular AV connection with separate AV junctions. A common junction (with an AV septal defect) is seen in approximately 30% of cases of left isomerism and in more than 90% of hearts with right isomerism. Concordant ventriculoarterial connections predominate in left isomerism, and a double-outlet right ventricle with an anterior aorta is most frequently seen in those with right isomerism. The venous connections are variable. These variations significantly affect the clinical and interventional management of these patients.

Isomerism of the Right Atrial Appendages

CLINICAL FEATURES. Bilateral “right-sidedness” results in a pattern of visceral abnormalities sometimes described as asplenia syndrome. The liver is midline, both lungs are trilobed with symmetrically short bronchi on the chest radiograph, and the spleen is hypoplastic or absent. The latter mandates immunization against pneumococcal infection and continuous penicillin prophylaxis against gram-positive sepsis. The diagnosis can be inferred from the bronchial pattern on the chest radiograph but most often is established by cross-sectional echocardiography because of the early development of severe CHD. Abdominal scanning shows the ipsilateral arrangement of the aorta and an anterior inferior vena cava. The intracardiac anatomy is most often that of an AV septal defect with varying degrees of right ventricular dominance, and an associated double-outlet right ventricle with an anterior aorta and subpulmonary stenosis or atresia is frequently present. Thus cyanosis is the most common finding. The inferior vena cava may connect to either right atrium, and the superior venae cavae are often lateralized and separate. It is the pulmonary venous drainage that is crucial to the features and outcome of these children. By definition the pulmonary veins are draining anomalously to one or the other right atrium, but this is frequently indirect and/or obstructed. Adequate repair of the latter is fundamental to achieving a good outcome in these children, who almost uniformly ultimately require a Fontan procedure.

MANAGEMENT OPTIONS AND OUTCOMES. Initial palliation is usually directed toward regulating pulmonary blood flow and dealing with anomalies of pulmonary venous connection. Subsequently these patients (even when they have equal-sized ventricles) are treated along a Fontan algorithm because repair of a complete AV septal defect in the setting of abnormal ventriculoarterial connections is technically difficult or impossible. Thus a unilateral or bilateral superior cavopulmonary anastomosis is performed at approximately 6 months of age, followed when possible by a Fontan procedure when 2 to 4 years of age.

The long-term outcome of surgery for right isomerism, however, has been poor. Improved early palliation and a staged approach directed toward the Fontan procedure have led to improved results. The prognosis for these infants, particularly those with obstruction to pulmonary venous return, must remain guarded.

Isomerism of the Left Atrial Appendages

CLINICAL FEATURES. These patients have bilateral “left-sidedness.” Hence they have two left lungs and bronchi, tend to have polysplenia, and frequently have malrotation of the gut. The cardiac abnormalities tend to be less severe than those of right isomerism. These patients are particularly prone to the development of atrial arrhythmias because the normal sinoatrial node is a right atrial structure and is usually absent in these patients. The ECG often shows an abnormal P wave axis, or wandering pacemaker. Complete heart block may also occur. The anatomic diagnosis is generally established by echocardiography. The abdominal great vessels are both to the right or to the left of the spine, as with right isomerism, but in left isomerism the vein is a posterior azygos vein that continues to connect to a left- or right-sided superior vena cava. The intrahepatic inferior vena cava is absent in 90%, and in such circumstances the hepatic veins drain directly to the atria. The pulmonary venous connection needs to be defined precisely before any surgical intervention. Pulmonary arteriovenous malformations are not infrequently seen in patients with left isomerism. These malformations can lead to cyanosis in unoperated or operated patients. Intracardiac anatomy varies from essentially normal to complex. Again, AV septal defect (partial and complete) is overrepresented but with less frequent ventricular imbalance and abnormalities of ventriculoarterial connection.

MANAGEMENT OPTIONS. Biventricular repair is achieved in many more of these patients, albeit with the need for complex atrial baffle surgery to separate systemic and pulmonary venous return. The long-term outcome in patients with left isomerism is therefore much better than in those with right isomerism. The issues are much like those related to the type of surgery, but monitoring for arrhythmia needs to be even more intense than usual.

The Fontan Patient (Fig. 62-28A, B)

Background

As stated in the introduction to this section, the uncertain nature of the Fontan circulation and the frequency of its failure require that all patients be monitored regularly in a specialized center for CHD, and new symptoms should prompt early reevaluation in such a center.

Since its description for the surgical management of tricuspid atresia in 1971, the Fontan procedure has become the definitive palliative surgical treatment when biventricular repair is not possible. The principle is diversion of systemic venous return directly to the pulmonary arteries without passing through a subpulmonary ventricle. Over the years, many modifications of the original procedure have been described and performed, namely, direct atriopulmonary connection, total cavopulmonary connection, and an extracardiac conduit. Fenestration (4 to 5 mm in diameter) of the Fontan circuit into the left atrium is sometimes performed in high-risk patients at the time of surgery to permit right-to-left shunting and decompression of the Fontan circuit.

Pathophysiology. Elevation of central venous pressure and reduced cardiac output (sometimes at rest but always during exercise) are inevitable consequences of the Fontan procedure. Small adverse changes in ventricular function (particularly diastolic), circuit efficiency (elevated pulmonary resistance, obstruction, thrombosis), or the onset of arrhythmia all potentially lead to major symptomatic deterioration.

Although it is reasonable to describe patients after the Fontan procedure as existing in a form of chronic heart failure (because their right atrial pressure must be high), this is seldom due to marked systolic dysfunction. Indeed, a small elevation in ventricular diastolic pressure may be much more harmful. Thus it may be incorrect to treat these patients with traditional heart failure medications. In two randomized, blinded, placebo-controlled studies, ACE inhibition failed to improve ventricular function⁵⁸ or functional performance, and some indices worsened.

The more “streamlined” Fontan circulations (total cavopulmonary anastomosis, extracardiac conduit) that exclude the right atrium from the circulation have demonstrably better fluid dynamic properties and improved functional performance. Physical obstruction at any or all of the surgical anastomoses, the distal pulmonary arteries, or the

FIGURE 62-28 Modification of the Fontan operation. **A**, Direct atriopulmonary connection (1) for tricuspid valve atresia (2); VSD, oversewn (3); and patch closure of an ASD (4). **B**, Extracardiac conduit made of a Dacron graft bypassing the right atrium and connecting the inferior vena cava to the inferior aspect of the right pulmonary artery. The superior vena cava is anastomosed to the superior aspect of the right pulmonary artery. Ao = aorta; LA = left atrium; LV = left ventricle; PA = pulmonary artery; RA = right atrium. (**A**, From Mullins CE, Mayer DC: *Congenital Heart Disease: A Diagrammatic Atlas*. New York, Wiley-Liss, 1988; **B**, from Marcelletti C: Inferior vena cava-pulmonary artery extracardiac conduit: A new form of right heart bypass. *J Thorac Cardiovasc Surg* 100:228, 1990.)

pulmonary veins (often secondary to compression by a dilated right atrium) reduces circulatory efficiency, however. Similarly, the elevated pulmonary arteriolar resistance has adverse effects because pulmonary vascular resistance is the single biggest contributor to impairment of venous return and elevation of venous pressure. Relatively little is known about pulmonary vascular resistance late after the procedure, but it has been shown to be elevated in a significant number of patients and to be reactive to inhaled nitric oxide, thus suggesting pulmonary endothelial dysfunction.

Recently, beneficial effects on exercise performance were shown with bosentan⁵⁹ and sildenafil⁶⁰ treatment, but this remains to be confirmed in larger studies.

Clinical Features

Most patients ($\approx 90\%$) are in functional class I to II at 5 years' follow-up after a Fontan procedure. Progressive deterioration in functional status with time is the rule. Supraventricular arrhythmias such as atrial tachycardia, flutter, and fibrillation are common. Physical examination in an otherwise uncomplicated patient reveals an elevated, usually nonpulsatile jugular venous pulse, a quiet apex, a normal S_1 , and a single S_2 (the pulmonary artery having been tied off). A heart murmur should not be present, and identification of one may suggest the presence of systemic AV valve regurgitation or sub-aortic obstruction. Generalized edema and ascites may be a sign of protein-losing enteropathy (see later).

Complications and Sequelae

ARRHYTHMIA. Although often associated with marked symptomatic decline, atrial arrhythmias tend to reflect the consequences of the abnormalities in ventricular function and circulatory efficiency described earlier. The massively dilated right atrium after an atriopulmonary connection is commonly associated with atrial flutter and fibrillation (in 15% to 20% at 5 years' follow-up). Atrial flutter or fibrillation carries significant morbidity,⁶¹ can be associated with profound hemodynamic deterioration, and needs prompt medical attention. The combination of atrial incisions and multiple suture lines at the time of Fontan surgery along with increased right atrial pressure and size probably explains the high incidence of atrial arrhythmias in such patients. Patients at greater risk for atrial

tachyarrhythmias are those who underwent surgery at an older age and had poor ventricular function, systemic AV valve regurgitation, or increased pulmonary artery pressure. It has been suggested that the exclusion of the right atrium as a result of the elevated systemic venous pressure (as in total cavopulmonary connections or extracardiac conduits) leads to a decrease in the incidence of atrial arrhythmias.⁶² This apparent benefit may, however, be due exclusively to the shorter length of follow-up in this group of patients. Sinus node dysfunction and complete heart block can occur and require pacemaker insertion.

THROMBOSIS AND STROKE. The reported incidence of thromboembolic complications in the Fontan circuit varies from 6% to 25%, depending on the diagnostic method used and the length of follow-up. Thrombus formation may be related to the presence of supraventricular arrhythmias, right atrial dilation, right atrial "smoke," and the artificial material used to construct the Fontan circuit. Systemic arterial embolism in patients with and without a fenestrated Fontan circuit has also been described. Protein C deficiency has been reported in these patients and

may explain in part their propensity for thromboembolism. There is continuing debate on the role of anticoagulation, antiplatelet therapy, or both in the long-term management of these patients,⁶³ but most receive some form of therapy.

PROTEIN-LOSING ENTEROPATHY. Protein-losing enteropathy, defined as severe loss of serum protein into the intestine, occurs in 4% to 13% of patients after a Fontan procedure.⁶⁴ Patients have generalized edema, ascites, pleural effusion, and/or chronic diarrhea. Protein-losing enteropathy is thought to result principally from chronically elevated systemic venous pressure causing intestinal lymphangiectasia with consequent loss of albumin, protein, lymphocytes, and immunoglobulin into the gastrointestinal tract. The diagnosis is confirmed by finding low serum albumin and protein, a low plasma α_1 -antitrypsin level and lymphocyte count, and most important, high α_1 -antitrypsin stool clearance. It carries a dismal prognosis, with a 5-year survival rate of 46% to 59%.

RIGHT PULMONARY VEIN COMPRESSION/OBSTRUCTION. Right pulmonary vein obstruction or compression can occur as a result of the enlarged right atrium or the atrial baffle bulging into the left atrium and can lead to a vicious spiral of increased pulmonary artery pressure with further dilation of the right atrium.

FONTAN OBSTRUCTION. Stenosis or partial obstruction of the Fontan connection leads to exercise intolerance, atrial tachyarrhythmias, and right-sided heart failure. Sudden total obstruction (usually thrombotic) can be manifested as sudden death (Video 62-56).

VENTRICULAR DYSFUNCTION AND VALVULAR REGURGITATION. Progressive deterioration in systemic ventricular function, with or without progressive AV valve regurgitation, is common. Patients with morphologic systemic right ventricles may fare less well than those with morphologic left ventricles.

HEPATIC DYSFUNCTION. Mildly raised hepatic transaminase levels secondary to hepatic congestion are frequent but seldom clinically important.⁶⁵ Cirrhosis caused by chronic venous hypertension is increasingly being recognized, and monitoring for complications of cirrhosis should be initiated.⁶⁶

CYANOSIS. Worsening cyanosis may be related to worsening ventricular function, the development of venous collateral channels draining to the left atrium, or the development of pulmonary

**VIDEO 62-56**

A young woman with a Bjork modification of the Fontan procedure (right atrial-to-right ventricular conduit—unvalved) complained of exercise intolerance. She was found to have left pulmonary artery stenosis and a freely regurgitant conduit. The left pulmonary artery was treated with a stent and the conduit was treated with a Melody Valve (Medtronic Inc., Minneapolis).

arteriovenous malformations (especially if a classic Glenn procedure remains as part of the Fontan circulation). In Fontan patients with cirrhosis, hepatopulmonary syndrome may occur.⁶⁷

Laboratory Investigations

Electrocardiography. Sinus rhythm, atrial flutter, junctional rhythm, or complete heart block may be present. The QRS complex reflects the basic underlying cardiac anomaly. In patients with tricuspid atresia, left-axis deviation is the norm. In patients with univentricular hearts, the conduction pattern varies widely and depends on the morphology and relative position of the rudimentary chamber.

Chest Radiography. Mild bulging of the right lower heart border from a dilated right atrium is often seen in patients with an atriopulmonary connection.

Echocardiography. The presence or absence of right atrial stasis, thrombus, patency of a fenestration, and obstruction of the Fontan circuit should be sought. Superior and inferior venae cava biphasic and pulmonary artery triphasic flow patterns suggest unobstructed flow in the Fontan circuit, whereas a mean gradient between the Fontan circuit and the pulmonary artery of 2 mm Hg or greater may represent significant obstruction. Assessment of the pulmonary venous flow pattern is important in detecting pulmonary vein obstruction (right pulmonary vein > left pulmonary vein) sometimes caused by an enlarged right atrium. Concomitant assessment of systemic ventricular function and AV valve regurgitation can readily be accomplished. TEE may be required if visualization of the Fontan anastomosis is inadequate or to exclude thrombus in the right atrium.

Magnetic Resonance Imaging. The objectives of MRI in Fontan patients include assessment of the pathways from the systemic veins to the pulmonary arteries for obstruction and thrombus; detection of Fontan baffle fenestration or leaks; evaluation of the pulmonary veins for compression; assessment of systemic ventricular volume, mass, and ejection fraction; imaging of the systemic ventricular outflow tract for obstruction; and quantitative assessment of the AV and semilunar valves for regurgitation and the aorta for obstruction or an aneurysm and evaluation for aortopulmonary, systemic venous, or systemic-to-pulmonary venous collateral vessels.

Diagnostic Catheterization. Complete heart catheterization is advised if surgical reintervention is planned or if adequate assessment of the hemodynamics is not obtained by noninvasive means.

Management Options and Outcomes

Patient selection for the Fontan procedure is of utmost importance and has a major impact on clinical outcome. The long-term survival rate in “ideal” candidates is 81% at 10 years versus 60% to 71% in “all comers.” Death occurs mostly from congestive heart failure and atrial arrhythmias. The Fontan procedure remains a palliative, not curative procedure. A more radical approach to a failing atriopulmonary Fontan circulation, including surgical revision of the circuit to an extracardiac conduit in combination with a Cox-maze procedure and, frequently, simultaneous epicardial pacemaker insertion, has recently been shown to provide good early and midterm palliation. Ultimately, cardiac transplantation may be required by some of these patients, although outcomes are less favorable in such patients.^{9,10}

ARRHYTHMIAS. Atrial tachyarrhythmias are quite difficult to manage and should quickly raise the thought of long-term warfarin therapy. When atrial flutter or fibrillation is present, an underlying hemodynamic cause should always be sought, and in particular, obstruction of the Fontan circuit needs to be excluded. Prompt attempts should be made to restore sinus rhythm. Antiarrhythmic medications, alone or combined with an epicardial antitachycardia pacing device, and radiofrequency catheter ablation techniques have had limited success. Surgical conversion from an atriopulmonary Fontan to a total cavopulmonary connection with concomitant atrial cryoablation therapy at the time of surgery has been reported with good medium-term success. Epicardial pacemaker insertion for sinus node dysfunction and/or complete heart block may be necessary. Epicardial AV sequential pacing should be used whenever possible.

ANTICOAGULANT THERAPY. The use of prophylactic long-term anticoagulation is contentious.⁶³ Experts recommend that patients with a history of documented arrhythmias, fenestration in the Fontan connection, or spontaneous contrast material (smoke) in the right

atrium on echocardiography be anticoagulated. For established thrombus, thrombolytic therapy versus surgical removal of the clot and conversion of the Fontan circuit has been described, both with high mortality rates (Video 62-57).

PROTEIN-LOSING ENTEROPATHY. Treatment modalities include a low-fat, high-protein, medium-chain triglyceride diet to reduce intestinal lymphatic production; albumin infusions to increase intravascular osmotic pressure; and/or the introduction of diuretics, afterload-reducing agents, and positive inotropic agents to lower central venous pressure. Most often these therapies are ineffective and should not be continued, if indeed tried at all. Catheter-based interventions such as balloon dilation of pathway obstruction or creation of an atrial fenestration, as well as surgical interventions ranging from conversion or takedown of the Fontan circuit to cardiac transplantation, have also been advocated. Other reportedly effective treatment modalities include subcutaneous heparin, octreotide treatment, and steroid therapy. All therapies have a similar failure rate of approximately 50%.

RIGHT PULMONARY VEIN COMPRESSION/OBSTRUCTION. When hemodynamically significant, Fontan conversion to a total cavopulmonary connection or extracardiac conduit may be recommended.

FONTAN OBSTRUCTION. Surgical revision of an obstructed right atrium to pulmonary artery or superior and inferior venae cavae to pulmonary artery connection is recommended, usually to an extracardiac Fontan circuit. Alternatively, balloon angioplasty with or without stenting may be used when appropriate and feasible (Videos 62-58 and 62-59).

VENTRICULAR FAILURE AND VALVULAR REGURGITATION. ACE inhibitors are of unproven benefit,⁵⁸ do not appear to enhance exercise capacity, and may cause clinical deterioration in Fontan patients. Patients with systemic AV valve regurgitation may require AV valve repair or replacement. Cardiac transplantation should also be considered.

CYANOSIS. In the setting of a fenestrated Fontan circuit, surgical or, preferably, transcatheter closure of the fenestration can be attempted. Pulmonary arteriovenous fistulas from a classic Glenn shunt may be improved by surgical conversion to a bidirectional Glenn connection.

Reproductive Issues

The rather fixed cardiac output and low-flow state of a Fontan circuit makes pregnancy rather problematic in these patients. Cardiovascular complications, including arrhythmias and venous congestion, as well as obstetric complications such as preterm labor and intrauterine growth retardation,⁶⁸ mandate a multidisciplinary high-risk pregnancy team approach to managing these patients once they are pregnant.

Follow-Up

Close and expert follow-up is recommended with particular attention to ventricular function and systemic AV valve regurgitation. The development of atrial tachyarrhythmia should instigate a search for possible obstruction at the Fontan anastomosis, right pulmonary vein obstruction, or thrombus within the right atrium. Some institutions have developed multidisciplinary Fontan clinics to advance both clinical research and patient care.

Total Anomalous Pulmonary Venous Connection Definition

This describes the situation in which all pulmonary veins fail to connect directly to the morphologic left atrium. As a result, all of the systemic and pulmonary venous return usually drains to the right atrium, albeit using varied routes.

Morphology (Fig. 62-29A-D). The anatomic varieties of total anomalous pulmonary venous connection may be subdivided, depending on the path of the abnormal drainage. The anomalous connection is most often supradiaphragmatic and connects via a vertical vein to the left brachiocephalic vein, directly to the right atrium, to the

**VIDEO 62-57**

A 35-year-old woman who had undergone a lateral-tunnel Fontan procedure was evaluated because of a 3-month history of worsening cyanosis and heart failure after atrial flutter developed. A pulmonary embolism occluding her left pulmonary artery was diagnosed. Angiography in the lateral tunnel suggested ongoing atrial arrhythmia. The lesion was managed percutaneously with balloon angioplasty and rheolytic thrombectomy. The lower lobe branch was retrieved, and lung circulation improved with further anticoagulation.

VIDEO 62-58

This child had undergone an extracardiac Fontan operation, but significant left pulmonary artery stenosis developed. In the first sequences, attempts were made to dilate the vessel with a conventional angioplasty balloon, but a persistent waist was present. A cutting balloon was then used to score the vessel, and subsequent balloon dilations were performed successfully. The gradient fell from 4 to 1 mm Hg across the vessel.

VIDEO 62-59

Young adult with a complication immediately after undergoing a Fontan completion procedure. Note the drains present in the cines. Angiography revealed that the conduit placed from the inferior vena cava to the pulmonary arteries was kinked, resulting in poor venous flow from the lower body. This was treated by stent implantation.

FIGURE 62-29 Anatomic types of total anomalous pulmonary venous return: supracardiac, in which the pulmonary veins drain either via the vertical vein to the anomalous vein (**A**) or directly to the superior vena cava (SVC) with the orifice close to the orifice of the azygos vein (**B**). **C**, Drainage into the right atrium via the coronary sinus. **D**, Infracardiac drainage via a vertical vein into the portal vein or the inferior vena cava (IVC). PT = pulmonary trunk. (From Stark J, de Leval M: *Surgery for Congenital Heart Defects*. 2nd ed. Philadelphia, WB Saunders, 1994, p 330.)

coronary sinus, or directly to the superior vena cava. In approximately 10% to 15% the pathway is below the diaphragm. The anomalous trunk then connects into the portal vein or one of its tributaries, the ductus venosus, or rarely, the hepatic or other abdominal veins.

Pathophysiology. The physiologic consequences and, accordingly, the clinical picture depend on the size of the interatrial communication and the degree of obstruction elsewhere within the pathway. When the interatrial communication is small, systemic blood flow is severely limited with right-sided heart failure. Obstruction to pulmonary venous return and pulmonary venous hypertension are invariably present in patients with an infradiaphragmatic anomalous pulmonary venous connection.

Natural History

Most patients with a total anomalous pulmonary venous connection have symptoms during the first year of life, and 80% die before 1 year of age if not treated. The presence of obstruction in the pulmonary venous pathway or at the atrial septum leads to earlier management. When the obstruction is severe, severe cyanosis and cardiovascular collapse in the neonatal period may occur. This is incompatible with survival without urgent surgical intervention.

Clinical Features

Symptomatic infants with a total anomalous pulmonary venous connection have signs of heart failure and/or cyanosis. Infants with pulmonary venous obstruction have an early onset of severe dyspnea, pulmonary edema, cyanosis, and right-sided heart failure. When unobstructed, the cyanosis may be minimal and go undetected. Auscultation generally reveals a fixed, widely split second heart sound with an accentuated pulmonic component.

Laboratory Investigations

Electrocardiography. The ECG usually shows right axis deviation and right atrial and right ventricular hypertrophy.

Chest Radiography. In an unrepaired patient, chest radiographs generally show cardiomegaly with increased pulmonary blood flow.

The right atrium and ventricle are dilated and hypertrophied, and the pulmonary artery segment is enlarged. The so-called figure-of-8 or snowman heart is due to enlargement of the heart and the presence of a dilated right superior vena cava, innominate vein, and left vertical vein.

Echocardiography (Fig. 62-30A-C). This usually shows marked enlargement of the right ventricle and a small left atrium. Demonstration of the entire pathway of pulmonary venous drainage is usually possible, and cardiac catheterization (which may be hazardous) is almost never performed now. An echo-free space representing the pulmonary venous confluence can generally be seen behind the left atrium. The drainage of all four pulmonary veins and their connections must be identified.

Magnetic Resonance Imaging. Although not often used, especially in infants, MRI may be helpful in older children to delineate the site of connections of total anomalous pulmonary venous return when there are multiple mixed sites and to detect stenosis in postoperative patients.

Indications for Intervention

Medical therapy, other than mechanical ventilation, has a limited role in symptomatic infants, and corrective surgery should be performed as soon as possible. In asymptomatic children without pulmonary hypertension, surgery can be deferred to 3 to 6 months of age.

Interventional Options and Outcomes

Occasionally, urgent balloon atrial septostomy is required to increase systemic blood flow before surgery. Otherwise, interventional catheterization is restricted to attempts at relieving postoperative pulmonary venous stenosis, although this is often unrewarding. Historically, surgical repair of restenosis was also disappointing. However, a sutureless technique whereby the pulmonary veins are opened widely into the retroatrial space has markedly improved the results of such surgery. Adult patients have almost always undergone surgical repair in childhood. As a rule, they function normally and are not too prone to arrhythmias or other problems. They are considered low-risk adults.

Follow-Up

Early follow-up should be frequent and aimed at early detection of stenosis of the pulmonary veins or the surgical anastomosis. If not present within the first year, stenosis is rare, but annual follow-up during childhood is required.

Transposition Complexes

The key anatomic feature that characterizes this group of diagnoses is ventriculoarterial discordance. It is most commonly seen in the context of AV concordance, also known as *complete transposition* or *D-TGA*. The second condition that is discussed in this section is the combination of ventriculoarterial discordance with AV discordance, commonly referred to as *cc-TGA* or *L-TGA*. More complicated arrangements are not considered here.

Complete Transposition of the Great Arteries

DEFINITION AND NATURAL HISTORY. D-TGA is a common and potentially lethal form of heart disease in newborns and infants. The malformation consists of the origin of the aorta from the morphologic right ventricle and that of the pulmonary artery from the morphologic left ventricle. Consequently the pulmonary and systemic circulations are connected in parallel rather than the normal in-series connection. In one circuit, systemic venous blood passes to the right atrium, the right ventricle, and then to the aorta and back to the systemic veins. In the other, pulmonary venous blood passes through the left atrium and ventricle to the pulmonary artery and then back to the pulmonary veins. This situation is incompatible with life unless mixing of the two circuits occurs.

Approximately two thirds of patients have no major associated abnormalities (*“simple” transposition*), and a third have associated abnormalities (*“complex” transposition*). The most common associated abnormalities are VSD and pulmonary/subpulmonary stenosis. It is increasingly being diagnosed in utero. Without treatment,

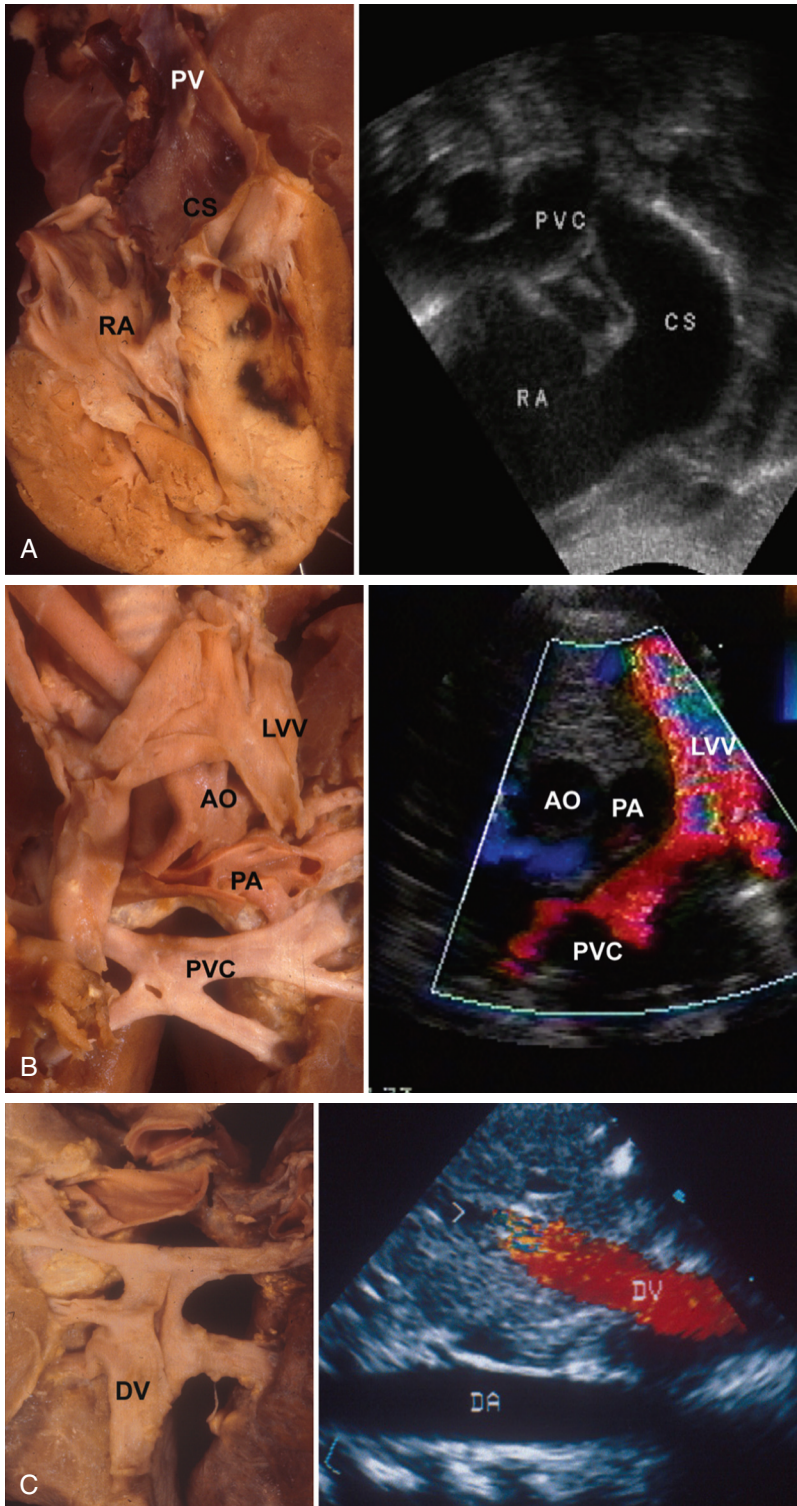

FIGURE 62-30 **A**, Subcostal view demonstrating total anomalous pulmonary drainage to the coronary sinus. Note the dilated coronary sinus on both images. The echocardiogram also demonstrates an associated confluence that connects to the coronary sinus. **B**, Suprasternal view demonstrating total anomalous pulmonary venous drainage to a left vertical vein. Note the direction of flow in the vertical vein, which differentiates it from a left superior vena cava. **C**, Total anomalous pulmonary venous drainage below the diaphragm. The specimen shows the pulmonary veins as they enter the confluence, whereas the echocardiogram demonstrates the descending veins as they enter the liver. Note that the direction of flow is away from the heart. AO = aorta; CS = coronary sinus; DA = descending aorta; DV = descending vein; LVV = left vertical vein; PA = pulmonary artery; PV = pulmonary vein; PVC = pulmonary venous confluence; RA = right atrium.

approximately 30% of these infants die within the first week of life, and 90% die within the first year.

Morphology. Some communication between the two circulations must exist after birth to sustain life. Almost all patients have an interatrial communication, blood flow across which governs the amount of desaturation. Two thirds have a PDA, and approximately a third have an associated VSD.

Pathophysiology. The degree of tissue hypoxia, the nature of the associated cardiovascular anomalies, and the anatomic and functional status of the pulmonary vascular bed determine the clinical course. The anatomic arrangement results in two separate and parallel circulations. Systemic arterial oxygen saturation is governed by the amount of blood exchanged between the two circulations. Infants with D-TGA are particularly susceptible to the early development of pulmonary vascular obstructive disease even in the absence of a PDA and even with an intact ventricular septum.

CLINICAL FEATURES. The average birth weight of infants born with D-TGA is greater than normal. The usual clinical manifestations are dyspnea and cyanosis from birth, progressive hypoxemia, and congestive heart failure. The most severe cyanosis and hypoxemia are observed in infants who have only a small PFO or ductus arteriosus and an intact ventricular septum or in infants with relatively reduced pulmonary blood flow because of left ventricular outflow tract obstruction. With a large ASD or PDA or a large VSD, cyanosis can be minimal, and heart failure is usually the dominant problem after the first few weeks of life. Cardiac murmurs are of little diagnostic significance.

A two-dimensional echocardiogram should establish the complete diagnosis, including the coronary artery pattern. Prenatal detection is possible and favorably modifies neonatal morbidity and mortality. Ultrasound imaging has become a standard procedure to guide catheter placement and manipulation during balloon atrial septostomy and to assess the anatomic adequacy of the septostomy.

MANAGEMENT OPTIONS. Maintenance of ductal patency with prostaglandin E_1 in the early neonatal period improves arterial saturation by enhancing mixing at the arterial level. This is usually done as a prelude to the creation or enlargement of an interatrial communication via a balloon or blade atrial septostomy. Surgical atrial septectomy is seldom required now.

SURGERY. Although balloon atrial septostomy is often lifesaving, it is palliative and anticipates “corrective” surgery. Atrial redirection procedures were developed in the 1950s and 1960s but were replaced by the arterial switch operation, which became widely adopted in the 1980s.

ATRIAL SWITCH (Fig. 62-31). The most common surgical procedure in patients who are older adults is the atrial switch operation. Patients will have undergone either a Mustard or a Senning procedure. Blood is redirected at the atrial level by using a baffle made of Dacron or pericardium (Mustard operation) or atrial flaps (Senning operation) to achieve physiologic correction. Systemic venous return is diverted through the mitral valve into the subpulmonary left ventricle, and pulmonary venous return is rerouted through the tricuspid valve into the subaortic right ventricle. By virtue of this repair, the morphologic right ventricle supports the systemic circulation.

PALLIATIVE ATRIAL SWITCH (Videos 62-60 through 62-64). Uncommonly, in patients with a large VSD and established pulmonary vascular disease, a palliative atrial switch operation is done to improve oxygenation.

**VIDEO 62-60**

Postoperative view of a palliative Senning procedure. This sweep shows the systemic and pulmonary venous pathways after a Senning procedure. Note that there is some mild increased flow velocity in the midportion of the pulmonary venous pathway.

VIDEO 62-61

VIDEO 62-63

Postoperative view of a palliative Senning procedure. This loop shows the tricuspid valve after a palliative Senning procedure in a patient with a large hypertensive VSD.

VIDEO 62-64

Postoperative view of a palliative Senning procedure. This real-time three-dimensional image shows good tricuspid valve coaptation in this patient.

The VSD is left open or enlarged at the time of atrial baffle surgery. These patients resemble those with Eisenmenger VSDs and should be managed as such.

ARTERIAL SWITCH OPERATION (Fig. 62-32A-D). In this operation the arterial trunks are transected and reanastomosed to the contralateral root. If present, a VSD is closed. The coronary arteries must be transposed to the neo-aorta. This is the most challenging part of the procedure and accounts for most of the mortality. Nonetheless, this rate has fallen to less than 2% in most large centers. The major advantages of the arterial switch procedure, when compared with the atrial switch procedure, are restoration of the left ventricle as the

systemic pump and the potential for long-term maintenance of sinus rhythm.

Follow-up studies after the arterial switch operation have demonstrated good left ventricular function and normal exercise capacity. Potential sequelae of the operation include coronary occlusion; supraventricular pulmonary stenosis (which may be treated by either reoperation or balloon angioplasty); supraventricular aortic stenosis; ascending aortic aneurysms; and neo-aortic regurgitation, usually mild.⁶⁹⁻⁷¹ Long-term patency and growth of the coronary arteries appear to be satisfactory.

RASTELLI PROCEDURE (Videos 62-65 through 62-67). Infants with TGA plus a VSD and left ventricular outflow tract obstruction may require an early systemic-to-pulmonary artery shunt when a pronounced diminution in pulmonary blood flow exists. A later corrective procedure for these patients bypasses the left ventricular outflow obstruction with an extracardiac prosthetic conduit between the right ventricle and the distal end of a divided pulmonary artery and uses an intracardiac ventricular baffle to tunnel the left ventricle to the aorta (Rastelli procedure). Late outcomes after the Rastelli procedure are particularly poor (see later), and in recent years another procedure, the Nikaidoh operation, has replaced the Rastelli procedure for some forms of TGA with VSD and pulmonary stenosis. In this operation the pulmonary outflow tract is resected and the aorta translocated posteriorly to sit more "anatomically" above the left ventricle, thus making subsequent left ventricular outflow tract obstruction less likely. Just as with the Rastelli procedure, the right ventricular outflow tract is reconstructed with a conduit in this operation, but because of the backward translocation of the aorta there is more space behind the sternum, and the hope is that conduit longevity will be enhanced.

MANAGEMENT OUTCOMES

ATRIAL SWITCH. After atrial baffle surgery, most patients who reach adulthood are in NYHA Classes I and II, but in many, abnormalities in ventricular filling because of the abnormal atrial pathways may be of more direct importance to functional capacity than right ventricular performance issues. Some are initially found to have symptoms of congestive heart failure (2% to 15%). Echocardiographic evidence of moderate or severe systemic right ventricular dysfunction is present in up to 40% of patients. Relative right ventricular ischemia (supply-demand mismatch) is thought to perhaps play a role in the systemic right ventricular dysfunction. More than mild systemic tricuspid regurgitation is present in 10% to 40%, both reflecting and exacerbating the right ventricular dysfunction. Palpitations and near-syncope/syncope from rhythm disturbances are fairly common.

Atrial flutter develops in 20% of patients by 20 years of age, and sinus node dysfunction is seen in half of the patients by that time. These rhythm disturbances are a consequence of direct and indirect atrial and sinus node damage at the time of atrial baffle surgery.

A shortened life expectancy is the rule, with a 70% to 80% survival rate at 20 to 30 years' follow-up. Patients with "complex" TGA in general fare worse than do those with "simple" TGA. Sudden cardiac death may occur in these patients and may be related to systemic right ventricular dysfunction, the presence of atrial flutter, and/or pulmonary hypertension. Significant pulmonary vascular disease can develop over time and is associated with older age at the time of the atrial switch operation, particularly in patients with a substantial VSD, as well as in those with longstanding left-to-right shunts through a baffle leak. Superior vena cava or inferior vena

FIGURE 62-31 Diagrammatic representation of atrial switch surgery (Mustard/Senning procedure). Superior vena cava (SVC) and inferior vena cava (IVC) blood is redirected into the morphologic left ventricle (LV), which pumps blood into the pulmonary artery (PA), whereas pulmonary venous blood flow is rerouted to the morphologic right ventricle (RV), which empties into the aorta (Ao). LA = left atrium; RA = right atrium; 1 = transposition of the great arteries; 2 = atrial baffles; 3 = pulmonary vein blood flow through the tricuspid valve to the RV; 4 = IVC and SVC blood flow through the mitral valve to the LV. (From Mullins CE, Mayer DC: *Congenital Heart Disease: A Diagrammatic Atlas*. New York, Wiley-Liss, 1988.)

FIGURE 62-32 Complete transposition of the great arteries corrected by a modified arterial switch operation (A). The aorta and pulmonary artery are transected, and the orifices of the coronary arteries are excised with a rim of adjacent aortic wall (B). The aorta is brought under the bifurcation of the pulmonary artery, and the pulmonary artery and the aorta are anastomosed without necessitating graft interposition. The coronary arteries are transferred to the pulmonary artery (C). The mobilized pulmonary artery is directly anastomosed to the proximal aortic stump (D). (From Stark J, de Leval M: *Surgery for Congenital Heart Defects*. New York, Grune & Stratton, 1983, p 379.)

cava baffle obstruction often goes undetected because collateral drainage through the azygos vein prevents systemic venous congestion. Pulmonary venous baffle obstruction causes elevated pulmonary artery pressure, and patients can exhibit dyspnea and features of pulmonary venous congestion.

Physical examination of a patient whose condition is otherwise uncomplicated reveals a right ventricular parasternal lift, a normal S_1 , a single S_2 (P_2 is not heard because of its posterior location), a pansystolic murmur from tricuspid regurgitation if present (best heard at the left lower sternal border, but not increasing with inspiration), and a right-sided S_3 when severe systemic ventricular dysfunction is present.

ARTERIAL SWITCH. Data on long-term complications in adults who have undergone the arterial switch procedure are emerging.⁷²⁻⁷⁵ The development of progressive neo-aortic valve regurgitation as a result of neo-aortic root dilation is the most common long-term sequela. It is time dependent and therefore requires periodic follow-up.^{70,71} Supra-neopulmonary artery stenosis is a frequent finding but rarely has clinical consequences. The development of ostial coronary artery disease has also been described in some patients.⁶⁹ Arrhythmia has the potential to be less of a problem in this group of patients. Findings on cardiac examination in uncomplicated patients are normal.

RASTELLI. When compared with either the arterial switch or the Mustard procedure, survival after the Rastelli procedure is poor, and the need for repeated intervention is high. Progressive right ventricle-to-pulmonary artery conduit obstruction can cause exercise intolerance or right ventricular angina. Left ventricular tunnel obstruction is frequent and can be manifested as exertional dyspnea or syncope. Conduit replacement or transcatheter stent or stent-valve implantation is inevitably required in surviving patients.^{76,77} Physical examination in uncomplicated patients reveals, in contrast to those after atrial switch, no right ventricular lift, an ejection systolic murmur from the conduit, and two components of the S_2 .

Laboratory Investigations

Electrocardiography. Sinus bradycardia or junctional rhythm (without a right atrial overload pattern) with evidence of marked right ventricular hypertrophy is characteristically present in patients after the atrial switch procedure. Findings on the ECG are typically normal in patients after the arterial switch procedure. The ECG generally shows a right bundle branch block after a Rastelli procedure.

Chest Radiography. On the posteroanterior view, a narrow vascular pedicle with an oblong cardiac silhouette ("egg on side") is typically seen in patients after the atrial switch procedure. On the lateral view the anterior aorta may be seen to fill the retrosternal space. For the arterial switch procedure, normal mediastinal borders are present despite the Leconte maneuver. After the Rastelli procedure, findings on the chest radiograph may be normal unless the conduit becomes calcified.

Echocardiography (Videos 62-68 through 62-70). After the atrial switch procedure, parallel great arteries are the hallmark of TGA (Fig. 62-33). They are best visualized on a parasternal long-axis view (running side by side) or on a parasternal short-axis view (seen en face, with the aorta anterior and rightward). Qualitative assessment of systemic right ventricular function, the degree of tricuspid regurgitation, and the presence or absence of subpulmonary left ventricular obstruction (dynamic or fixed) is important. Assessment of baffle leak or obstruction (Fig. 62-34) is best done with color and Doppler flow imaging. Normal baffle flow should be phasic in nature and vary with respiration, with a peak velocity of less than 1 meter/sec. After arterial

FIGURE 62-33 Parasternal long-axis view of TGA. Note the parallel nature of the aorta and pulmonary artery. AO = aorta; LV = left ventricle; PA = pulmonary artery; RV = right ventricle.

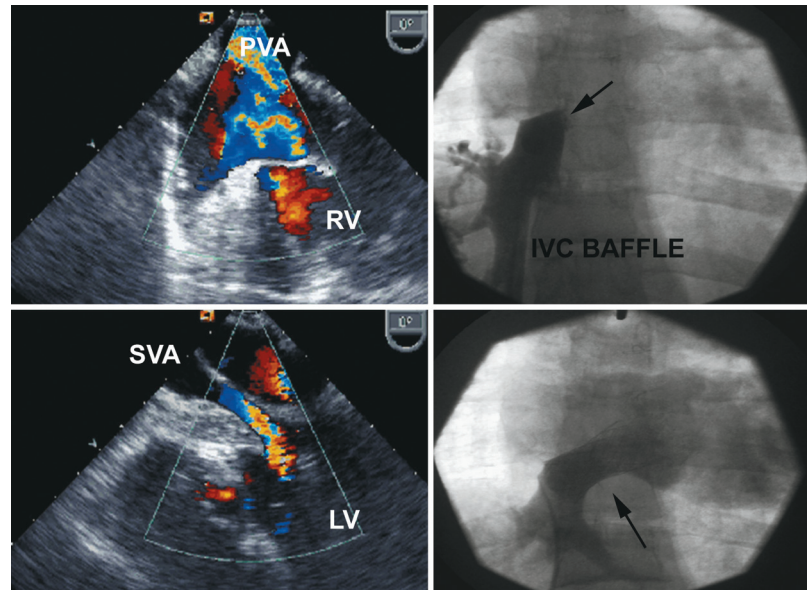

FIGURE 62-34 Montage of post-Mustard procedure cases. The angiogram in the **right upper** panel shows complete obstruction of the inferior limb of the systemic venous baffle, whereas the **lower right** panel is the same case after stenting. The **upper left** image is a transesophageal echocardiogram showing the pulmonary venous baffle with some mild flow acceleration in its midpoint. The **lower left** panel shows the systemic venous baffle at its left ventricular end. IVC = inferior vena cava; LV = left ventricle; PVA = pulmonary venous atrium; RV = right ventricle; SVA = systemic venous atrium.

switch, neo-aortic valve regurgitation, supra-neopulmonary valve stenosis, and a segmental wall motion abnormality from ischemia because of coronary ostial stenosis should be sought. In patients who have undergone the Rastelli operation, left ventricle-to-aorta tunnel obstruction, as well as right ventricle-to-pulmonary artery conduit degeneration (stenosis/regurgitation), must be assessed.

Magnetic Resonance Imaging. The major role of MRI in patients with atrial switch is to evaluate the baffles and systemic right ventricular volume and ejection fraction. As a rule, MRI reports right ventricular size and function better than echocardiography does. For patients who are claustrophobic or have a pacemaker, CT angiography may serve as a substitute.

Cardiac Catheterization. Diagnostic cardiac catheterization may be required for assessing the presence or severity of systemic/pulmonary baffle obstruction, baffle leak, and pulmonary hypertension; coronary ostial stenosis; or tunnel or conduit obstruction when not diagnosed by noninvasive means.

INDICATIONS FOR REINTERVENTION. After the *atrial switch procedure*, severe symptomatic right ventricular dysfunction may warrant surgical treatment in the form of a *two-stage arterial switch procedure* or cardiac transplantation. Tricuspid valve repair or replacement is

**VIDEO 62-68**

VIDEO 62-70

Postoperative view of a patient after a Senning procedure with tricuspid valve regurgitation. This real-time three-dimensional loop shows the tricuspid valve from below. Note the relatively immobile part of the septal leaflet at the site of the anteroseptal commissure (between 12 and 3 o'clock).

rarely performed for severe systemic (tricuspid) AV valve regurgitation but may be appropriate if caused by a flail leaflet or cusp perforation, provided that right ventricular function is adequate. A baffle leak resulting in a significant left-to-right shunt ($>1.5:1$), any right-to-left shunt, or attributable symptoms requires surgical or transcatheter closure. Superior vena cava or inferior vena cava pathway obstruction may require intervention (Video 62-71). Superior vena cava stenosis is usually benign, whereas inferior vena cava stenosis may have greater hemodynamic consequences, depending on the adequacy of alternative routes of venous return, usually via the azygos vein to the superior vena cava. Balloon dilation of superior vena cava or inferior vena cava stenosis is an option in expert hands. Stenting generally relieves the stenosis completely.

Pathway obstruction after the Senning operation is usually more amenable to balloon dilation and stenting (see Video 62-71). Pulmonary venous obstruction, although generally seen early and reoperated on in childhood, may develop in adulthood. Symptomatic bradycardia warrants permanent pacemaker implantation, whereas tachyarrhythmias may require catheter ablation, an antitachycardia pacemaker device, or medical therapy. After an atrial switch, the transvenous pacing leads must traverse the upper limb of the baffle to enter the morphologic left ventricle. Active fixation is required because coarse trabeculation is absent in the morphologic left ventricle. Transvenous pacing should be avoided in patients with residual intracardiac communications because paradoxical emboli can occur.

After an *arterial switch procedure*, significant right ventricular outflow tract obstruction at any level (gradient >50 mm Hg or right-to-left ventricular pressure ratio >0.6) may require surgical or catheter augmentation of the right ventricular outflow tract. Myocardial ischemia secondary to coronary artery obstruction may require coronary artery bypass grafting, preferably with arterial conduits. Significant neo-aortic valve regurgitation may warrant aortic valve replacement.

In patients who have undergone the *Rastelli procedure*, significant right ventricle-to-pulmonary artery conduit stenosis (>50 -mm Hg withdrawal gradient or mean echocardiographic gradient) or significant regurgitation necessitates intervention. Subaortic obstruction across the left ventricle to the aorta tunnel necessitates left ventricle-to-aorta baffle reconstruction. A significant residual VSD (shunt $>1.5:1$) may require surgical closure.

REINTERVENTION OPTIONS

MEDICAL THERAPY. In patients who have undergone an atrial switch procedure, the role of afterload reduction with ACE inhibitors, angiotensin receptor blockers,⁷⁸⁻⁸⁰ or beta blockade^{81,82} to preserve systemic right ventricular function is unknown.

TWO-STAGE ARTERIAL SWITCH AND CARDIAC TRANSPLANTATION. Following an atrial switch procedure, patients with symptomatic, severe systemic (right) ventricular dysfunction with or without severe systemic (tricuspid) AV valve regurgitation may require consideration of a conversion procedure to an arterial switch (two-stage arterial switch) or heart transplantation. The two-stage arterial switch, or switch conversion procedure, consists of banding the pulmonary artery in the first stage to induce subpulmonary left ventricular hypertrophy and to “train” the left ventricle to support systemic pressure. Once left ventricular systolic pressure is more than 75% of systemic pressure and the left ventricular mass is considered adequate, the atrial baffles and the pulmonary band are taken down, the atrial septum is reconstructed, and the great arteries are switched, with the morphologic left ventricle being left as the systemic ventricle. This procedure is still experimental in adults, with few data available to assess its short- and long-term efficacy.

REPRODUCTIVE ISSUES. Severe systemic ventricular dysfunction or intractable arrhythmias may be a contraindication to pregnancy, and baffle obstruction should ideally be relieved before pregnancy. Women who have undergone an atrial switch procedure usually tolerate pregnancy well, but worsening right ventricular function or tricuspid regurgitation will develop in approximately 15% during the pregnancy.⁸³ In half of these cases the problem does not improve after delivery. Pregnancy after arterial switch is better tolerated, assuming that there are no significant hemodynamic lesions before pregnancy.⁸⁴

FOLLOW-UP. Regular follow-up by physicians with special expertise in CHD is recommended.

ATRIAL SWITCH. Serial follow-up of systemic right ventricular function is warranted. Asymptomatic baffle obstruction and leaks should be sought with echocardiography or MRI. Regular Holter monitoring is recommended to diagnose unacceptable bradyarrhythmias or tachyarrhythmias.

ARTERIAL SWITCH AND RASTELLI. Regular follow-up with echocardiography is recommended. As patients advance in age, MRI is more suited to assess the branch pulmonary arteries after the Lecompte maneuver because this is a challenging area to see with echocardiography (Fig. e62-5).

Congenitally Corrected Transposition of the Great Arteries

DEFINITION. The term *congenitally corrected transposition of the great arteries* describes hearts with discordant AV connections in combination with discordant ventriculoarterial connections.

Morphology (Fig. 62-35). cc-TGA is a rare condition that accounts for less than 1% of all CHD. When the usual atrial arrangement is present, systemic venous blood passes from the right atrium through a mitral valve to a left ventricle and then to the posteriorly located pulmonary artery. Pulmonary venous blood passes from the left atrium through a tricuspid valve to a left-sided right ventricle and then to an anterior, left-sided aorta. The circulation is thus “physiologically” corrected, but the morphologic right ventricle supports the systemic circulation. Associated anomalies occur in up to 95% of patients and consist of VSD (75%), pulmonary or subpulmonary stenosis (75%), and left-sided (tricuspid and often “Ebstein-like”) valve anomalies (75%).

Because of the inherently abnormal conduction system, 5% of patients with cc-TGA are born with congenital complete heart block.

Pathophysiology. Patients with no associated abnormalities (“isolated” cc-TGA) can exceptionally survive until the seventh or eighth decade. Progressive systemic (tricuspid) AV valve regurgitation and systemic (right) ventricular dysfunction tend to occur from the fourth decade onward, whereas atrial tachyarrhythmias are more common from the fifth decade onward. In addition to those born with congenital complete heart block, acquired complete AV block continues to develop at a rate of 2% per year, concentrated mainly at the time of cardiac surgery. Patients with associated anomalies (VSD, pulmonary

VIDEO 62-71

Young adult man with cyanosis and exercise intolerance after a remote Mustard operation for D-TGA. Noninvasive investigation suggested a superior baffle leak and near occlusion. Angiography was carried out above the stenosis and the leak, past the level of obstruction, and in the pulmonary venous baffle. A wire was used to cross the stenosis from above and was snared and exteriorized. The baffle leak was then crossed, balloon-sized, and closed with an Amplatzer (St. Jude Medical Inc., St. Paul, Minn) ASD device. The superior baffle was then treated with a large-vessel stent.

stenosis, left-sided [tricuspid] valve anomaly) have often undergone surgical palliation (systemic-to-pulmonary artery shunt for cyanosis) or repair of the associated anomalies (see Surgical Procedures), but a significant number of patients are naturally balanced by a combination of their VSD and subpulmonary left ventricular outflow tract obstruction. Although cyanosed, they often remain well, with no intervention needed for many years.

CLINICAL FEATURES

UNOPERATED. Patients with no associated defects can be asymptomatic until late adulthood. Dyspnea, exercise intolerance from developing congestive heart failure, and palpitations as a result of supraventricular arrhythmias most often arise in the fifth decade. Patients with well-balanced VSD and pulmonary stenosis can exhibit paradoxical emboli or cyanosis, especially if the pulmonary stenosis is severe. Physical examination of a patient whose condition is otherwise uncomplicated reveals a somewhat more medial apex because of the side-by-side orientation of the two ventricles. A_2 is often palpable in the second left intercostal space as a result of the anterior location of the aorta. A single S_2 (A_2) is heard, with P_2 often being silent because of its posterior location. The murmur of an associated VSD or left AV valve regurgitation may be heard. The murmur of pulmonary stenosis radiates upward and to the right, given the rightward direction of the main pulmonary artery. If a complete heart block is present, cannon “a waves” with an S_1 of variable intensity are present.

VENTRICULAR SEPTAL DEFECT PATCH AND LEFT VENTRICLE-TO-PULMONARY ARTERY CONDUIT REPAIR. Most patients are in NYHA functional class I at 5 to 10 years after surgery despite the common development of systemic tricuspid regurgitation and systemic right ventricular dysfunction after surgical repair. Dyspnea, exercise intolerance, and palpitations from supraventricular arrhythmia often occur in the fourth decade. Complete heart block may complicate surgery in an additional 25%. Physical examination reflects the basic cardiac malformation with or without residual coexisting anomalies.

Laboratory Investigations

Electrocardiography. An abnormal direction of the initial (septal) depolarization from right to left causes reversal of the precordial Q wave pattern (Q waves are often present in the right precordial leads and absent in the left). First-degree AV block occurs in approximately 50%, and complete AV block develops in up to 25% of patients. Atrial arrhythmias may be seen.

Chest Radiography. Chest radiography characteristically reveals absence of the normal pulmonary artery segment in favor of a smooth convexity of the left supracardiac border produced by the left-sided ascending aorta. The main pulmonary trunk is displaced medially and absent from the cardiac silhouette; the right pulmonary hilum is often prominent and elevated in comparison to the left, thereby producing a right-sided “waterfall” appearance.

Echocardiography (Fig. 62-36, and Videos 62-72 through 62-74). Echocardiography permits identification of the basic malformation, as well as any associated anomalies. The right-sided morphologic left ventricle is characterized by its smooth endocardial surface and is guarded by a bileaflet AV (mitral) valve with no direct septal attachment. The morphologic right ventricle is recognized by its apical trabeculation and moderator band and is guarded by a trileaflet apically displaced AV valve (tricuspid valve) with direct attachment to the septum. The AV valves therefore show reversed offsetting, a strong clue to the diagnosis. Ebstein-like malformation of the left (tricuspid) AV valve is defined by excessive (>8 mm/m² body surface area) apical displacement of the left (tricuspid) AV valve with or without dysplasia (Videos 62-75 through 62-79).

Magnetic Resonance Imaging. The major role of MRI in patients with cc-TGA is to evaluate systemic right ventricular volume and ejection fraction. It does so better than echocardiography can at present. For claustrophobic or pacemaker patients, a high-quality radionuclide angiogram or a CT angiogram with volume estimates may serve as a

FIGURE 62-36 Four-chamber view of cc-TGA with dysplasia and displacement of the morphologic left-sided tricuspid valve. LA = left atrium; MLV = morphologic left ventricle; MRV = morphologic right ventricle; RA = right atrium; TV = tricuspid valve.

substitute. MRI can evaluate other issues as well, including conduit function and AV valve regurgitation.

Cardiac Catheterization. This is rarely required for diagnosis but may be indicated before surgical repair to demonstrate the coronary artery anatomy, as well as ventricular end-diastolic and pulmonary artery pressure.

INDICATIONS FOR INTERVENTION AND REINTERVENTION. If moderate or severe systemic (tricuspid, left) AV valve regurgitation develops, valve replacement should be considered. Left AV valve replacement should be performed before systemic right ventricular function deteriorates, namely, at an ejection fraction of 45% or greater. When tricuspid regurgitation is associated with poor systemic (right) ventricular function, the double-switch procedure should perhaps be considered. Patients with end-stage symptomatic heart failure should be referred for cardiac transplantation. The presence of a hemodynamically significant VSD ($Q_p/Q_s > 1.5$) or residual VSD with significant native or postsurgical (conduit) pulmonary outflow tract stenosis (echocardiographic mean or catheter gradient >50 mm Hg) may require surgical correction, although the latter is sometimes best left alone because it can maintain a neutral septal position and minimize systemic tricuspid regurgitation. Left AV valve replacement at the time of surgery for a VSD and pulmonary stenosis should be considered if concomitant left AV valve regurgitation is present. Pacemaker implantation is usual when a complete AV block is present. The optimal pacing modality is DDD. Active fixation electrodes are required because of the lack of apical trabeculation in the morphologic left ventricle. Transvenous pacing should be avoided in those with intracardiac shunts because paradoxical emboli may occur.⁸⁵ Epicardial leads are preferred in these circumstances.

INTERVENTIONAL OPTIONS

MEDICAL THERAPY. ACE inhibitor, angiotensin receptor blocker, or beta blocker therapy for patients with systemic ventricular dysfunction may be intuitive, but the role of such agents has not yet been demonstrated conclusively.^{78,79,82,86}

CONDUIT REPLACEMENT OR REPAIR. This is inevitably required in survivors of this type of initial surgery. Fortunately, it is now possible in some patients and in many countries to repair a failing conduit with a percutaneously delivered stented valve.⁸⁷

TRICUSPID VALVE REPLACEMENT. Valve repair is usually unsuccessful because of the abnormal, often Ebstein-like anatomy of the valve. Consequently, for significant regurgitation, replacement is preferable to repair but carries higher risk if significant right ventricular dysfunction is present (ejection fraction $<45\%$).

DOUBLE-SWITCH PROCEDURE. This procedure has been performed successfully in children⁸⁸⁻⁹⁰ and carefully selected adults. It should be considered for patients with severe tricuspid regurgitation and systemic ventricular dysfunction. Its purpose is to relocate the left ventricle into the systemic circulation and the right ventricle into the pulmonary circulation to achieve physiologic correction. An

**VIDEO 62-72**

Corrected transposition with valve dysplasia but without displacement. This en face real-time three-dimensional tricuspid valve loop shows the three leaflets of the tricuspid valve with an area of poor coaptation centrally. ANT = anterior; POST = posterior; SEPT = septal.

VIDEO 62-73

Corrected transposition with valve dysplasia but without displacement. This real-time three-dimensional color loop is an en face view and shows that the regurgitant jet is situated more posteriorly between the septal and posterior leaflets.

VIDEO 62-74

Corrected transposition with valve dysplasia but without displacement. This sweep shows the large jet of regurgitation in a nondisplaced tricuspid valve.

VIDEO 62-75

Corrected transposition with tricuspid valve regurgitation. This is the image of a dysplastic and displaced tricuspid valve in a patient with corrected transposition of the great arteries. Note how tethered the septal leaflet is.

VIDEO 62-76

Corrected transposition with tricuspid valve regurgitation. This four chamber view shows a large regurgitant jet of the tricuspid valve in a patient with corrected transposition of the great arteries. There is leaflet displacement, described as an “Ebstein-like” malformation.

VIDEO 62-77

Corrected transposition with tricuspid valve regurgitation. This real-time three-dimensional image shows the three leaflets of the tricuspid valve and the commissures. AL = anterior leaflet; LV = left ventricle; PS = posterior leaflet; SL = septal leaflet.

VIDEO 62-78

Corrected transposition with tricuspid valve regurgitation. This real-time three-dimensional image shows the tricuspid valve from above. Note the displacement of the leaflets from the annulus, with the leaflets appearing more “blue,” thus indicating that they are further away from the more *brown* structures.

VIDEO 62-79

Corrected transposition with tricuspid valve regurgitation. This real-time three-dimensional color image shows the vena contracta as seen from the surgical view. Note that it is elongated and is due to poor leaflet coaptation.

atrial switch procedure (Mustard or Senning), together with either an arterial switch procedure (when pulmonary stenosis is not present) or a Rastelli-type repair, the so-called *Ilbawi procedure* (left ventricle tunneled to the aorta and a right ventricle-to-pulmonary artery valved conduit when VSD and pulmonary stenosis are present), can be performed after adequate left ventricular retraining, with the regurgitant tricuspid valve and failing right ventricle being left on the pulmonary side.

CARDIAC TRANSPLANTATION.

Patients with deteriorating systemic (right) ventricular function should be treated aggressively with medical therapy but may need to be considered for transplantation.

INTERVENTIONAL OUTCOMES.

After conduit repair and VSD patching, the median survival of patients reaching adulthood is 40 years. The usual causes of death are sudden (presumed arrhythmic) or, more commonly, progressive systemic right ventricular dysfunction with systemic (tricuspid) AV valve regurgitation. The major predictor of a poor outcome is the presence of left AV (tricuspid) valve regurgitation. Reoperation is common (15% to 25%), with left AV valve replacement usually being the primary reason. Data on the double-switch procedure in adults are lacking, and this procedure should be considered experimental in this patient population.

REPRODUCTIVE ISSUES. Severe systemic ventricular dysfunction or intractable arrhythmias may be a contraindication to pregnancy, and severe systemic tricuspid regurgitation or conduit problems should ideally be relieved before pregnancy. In women with a good functional capacity, pregnancy is usually well tolerated, but worsening tricuspid regurgitation or ventricular dysfunction or arrhythmias can occur and may be poorly tolerated.

FOLLOW-UP. All patients should undergo at least annual cardiology follow-up with an expert in the care of patients with congenital cardiac defects. Regular assessment of systemic (tricuspid) AV valve regurgitation by serial echocardiographic studies and systemic ventricular function by MRI or radionuclide angiography should be done. Holter recording can be useful if paroxysmal atrial arrhythmias or a transient complete AV block is suspected.

Double-Outlet Right Ventricle

Definition

The term *double-outlet right ventricle* describes hearts in which more than 50% of each semilunar valve arises from the morphologic right ventricle. It may coexist with any form of atrial arrangement or AV connection and is independent of infundibular (conal) anatomy.

Morphology (Fig. 62-37A, B). Few morphologic descriptors have invoked more discussion and controversy than has double-outlet right ventricle. The definition given above is flawed but pragmatic. To some extent this anatomic definition is less important than understanding the relationship between the great vessels and the VSD and the anatomy of the outlets to the great vessels, both of which are crucial determinants of the clinical features and management.

Clinical Features

Three main categories of double-outlet right ventricle exist: (1) double-outlet right ventricle with a subaortic VSD, (2) double-outlet right ventricle with a subpulmonary VSD, and (3) double-outlet right ventricle with a noncommitted VSD.

When present, the anatomy of the infundibular septum further modifies the hemodynamics. Taking a double-outlet right ventricle

FIGURE 62-37 A double-outlet right ventricle with a side-by-side relationship of the great arteries is illustrated in both panels. **A**, A subaortic VSD below the crista supraventricularis favors delivery of left ventricular blood to the aorta. **B**, A subpulmonary location of the VSD above the crista favors streaming to the pulmonary trunk. (From Castañeda A, Jonas RA, Mayer JE, et al: *Cardiac Surgery of the Neonate and Infant*. Philadelphia, WB Saunders, 1994, p 446.)

with a *subaortic VSD* as an example, in which the aorta and its semilunar valve are closest to or overriding the trabecular septum, anterior deviation of the outlet septum causes subpulmonary stenosis, and the clinical scenario and management algorithm are similar or identical to that for tetralogy of Fallot. Conversely, if the outlet septum is deviated posteriorly, subaortic stenosis will be present, often with a coexisting abnormality of the aortic arch. The clinical features and management of this variation are therefore entirely different. If there is no deviation of the outlet septum and no outlet obstruction, the clinical scenario will be that of a simple VSD. A double-outlet right ventricle with a *subpulmonary VSD* (Taussig-Bing anomaly) can be considered along with TGA because the usual position of the pulmonary artery (posterior and leftward to the aorta) means that the streaming of deoxygenated and oxygenated blood is similar to that of transposition, even though most of the pulmonary valve is connected to the right ventricle. Anterior deviation of the outlet septum causes subaortic stenosis and aortic anomalies, and posterior deviation causes subpulmonary stenosis and limits pulmonary blood flow. It is also important to recognize a double-outlet right ventricle with a *noncommitted VSD*. This defines hearts in which the VSD is remote from the outlets, thus making surgical management particularly difficult.

Associated Lesions

More than half of patients with double-outlet right ventricles have associated anomalies of the AV valves. Mitral valve stenosis or atresia associated with a hypoplastic left ventricle is common. Ebstein anomaly of the tricuspid valve, complete AV septal defect, and overriding or straddling of either AV valve may occur.

Laboratory Investigations. Because of diversity in the underlying anatomy, discussion of the electrocardiographic and radiographic features is not included here.

Echocardiography. This is the mainstay of diagnosis. Commitment of the semilunar valves to the ventricles is ascertained. When present, deviation of the outlet septum beneath a semilunar valve probably has implications for downstream development of the great vessels. For example, when subaortic stenosis is present, the echocardiographic examination is incomplete until abnormalities of the aortic arch have been excluded. Preoperative evaluation must also take into account potential AV valve anomalies and straddling in particular.

Indications for Intervention

The goals of operative treatment are to establish continuity between the left ventricle and aorta, create adequate right

ventricle-to-pulmonary artery continuity, and repair associated lesions. Palliative surgery is reserved for those in whom biventricular repair is not possible and in those with markedly reduced pulmonary blood flow. In the latter, an aortopulmonary shunt may be placed to temporize the patient's condition before complete correction. For the remainder, complete repair is now performed as a primary procedure in most. In double-outlet right ventricle with a subaortic VSD, repair is accomplished by creating an intraventricular baffle that conducts left ventricular blood to the aorta. If coexisting subpulmonary stenosis is present, the repair is similar to that for tetralogy of Fallot. When the VSD is subpulmonary but without subpulmonary stenosis, repair is accomplished by closure of the VSD and arterial switch. Subpulmonary stenosis is frequently present in a double-outlet right ventricle with a subpulmonary VSD. In these cases the aorta is connected to the left ventricle via an intraventricular baffle, and a right ventricle-to-pulmonary artery conduit is placed to complete the repair (Rastelli procedure). The classic surgical approaches cannot be used when the VSD is remote and uncommitted to either semilunar orifice. Occasionally, the VSD can be baffled toward the aorta, but when this is not possible, the right ventricle may be used as the systemic ventricle. This requires a Mustard or Senning atrial redirection procedure, closure of the VSD, and placement of a conduit between the left ventricle and pulmonary trunk.

Interventional Options and Outcomes

Late follow-up of the surgical procedures described earlier (e.g., tetralogy of Fallot repair, arterial switch, Rastelli) tends to be less satisfactory when a double-outlet right ventricle is present than when surgery is performed for more classic indications. The development of subaortic stenosis is more likely because of the abnormal geometry of the left ventricular outflow tract that often results after correction. Similarly, right ventricle-to-pulmonary artery conduit obstruction is more likely because of the spatial difficulties imposed on placement of the conduit with respect to the position on the right ventricle and the sternum. Because of these considerations, the options for catheter interventions are often fairly limited. However, recurrent arch obstruction and distal pulmonary artery obstruction are amenable to balloon dilation with or without stenting.

Follow-Up

All these patients require at least annual review by a congenital cardiologist.

Ebstein Anomaly

Morphology (Fig. 62-38). The common feature in all cases of Ebstein anomaly is apical displacement of the septal tricuspid leaflet in conjunction with leaflet dysplasia. Many, but not all, have associated displacement of the posterior mural leaflet, with the anterior leaflet never being displaced. Even though the anterior leaflet is never displaced apically, it may be adherent to the free wall of the right ventricle and cause right ventricular outflow tract obstruction. The displacement of the tricuspid valve results in "atrialization" (functioning as an atrial chamber) of the inflow tract of the right ventricle and consequently produces a variably small functional right ventricle. Associated anomalies include a PFO or ASD in approximately 50% of patients; accessory conduction pathways in 25% (usually right sided); and occasionally, varying degrees of right ventricular outflow tract obstruction, VSD, aortic coarctation, PDA, or mitral valve disease. Left ventricular abnormalities resembling noncompaction syndrome have also been described.

Pathophysiology. Varying degrees of tricuspid regurgitation (or exceptionally, tricuspid stenosis) result from the abnormal tricuspid leaflet morphology with consequent further right atrial enlargement. Right ventricular volume overload as a result of significant tricuspid regurgitation and infundibular dilation can also be present. Right-to-left shunting through a PFO or ASD occurs if right atrial pressure exceeds left atrial pressure (which is often the case when severe tricuspid regurgitation is present).

Natural History

The natural history of patients with Ebstein anomaly depends on its severity. When the tricuspid valve deformity and dysfunction are

FIGURE 62-38 Diagrammatic representation of the Ebstein anomaly. Ao = aorta; LA = left atrium; LV = left ventricle; PA = pulmonary artery; RA = right atrium; RV = right ventricle. (From Mullins CE, Mayer DC: *Congenital Heart Disease: A Diagrammatic Atlas*. New York, Wiley-Liss, 1988.)

extreme, death in utero from hydrops fetalis is the norm. When the tricuspid valve deformity is severe, symptoms usually develop in newborn infants. Patients with moderate tricuspid valve deformity and dysfunction generally have symptoms initially during late adolescence or young adult life. Adults with Ebstein anomaly can occasionally remain asymptomatic throughout life if the anomaly is mild—exceptional survival to the ninth decade has been reported.

Clinical Features

With severe tricuspid valve deformity, newborns and infants exhibit failure to thrive and right-sided congestive heart failure. In general, children initially seen after the neonatal period remain asymptomatic until late adolescence or early adult life. Most adult patients have exercise intolerance (exertional dyspnea and fatigue), palpitations of supraventricular origin, or cyanosis from a right-to-left shunt at the atrial level. Occasionally, a paradoxical embolus resulting in a transient ischemic attack or stroke can call attention to the diagnosis. Right-sided cardiac failure from severe tricuspid regurgitation and right ventricular dysfunction is possible. Sudden death (presumed to be arrhythmic in nature) has been described. Physical examination typically reveals normal jugular venous pressure because of the large and compliant right atrium and atrialized right ventricle, a widely split S_1 with a loud tricuspid component (the "sail sound"), a widely split S_2 from a right bundle branch block, and a right-sided third heart sound. A pansystolic murmur (typically increasing on inspiration) from tricuspid regurgitation is best heard at the lower left sternal border. Cyanosis from a right-to-left shunt at the atrial level may or may not be present.

Laboratory Investigations

Electrocardiography. Findings on the ECG in patients with Ebstein anomaly vary widely. Low voltage is typical. Peaked P waves in leads II and V_1 reflect right atrial enlargement. The PR interval is generally prolonged, but a short PR interval and a delta wave from early activation through an accessory pathway can be present. An rsr' pattern consistent with right ventricular conduction delay is typically seen in lead V_1 , and right bundle branch block is common in adults. Atrial flutter and fibrillation are common. Findings on the ECG may be normal.

Chest Radiography. A rightward convexity from an enlarged right atrium and atrialized right ventricle coupled with a leftward convexity

FIGURE 62-39 Apical four-chamber view of an Ebstein malformation of the tricuspid valve. Note the significant displacement of the septal tricuspid valve leaflet (asterisk) with associated valve dysplasia. LV = left ventricle; RA = right atrium; RV = right ventricle.

from a dilated infundibulum give the heart a “water bottle” appearance on chest radiography. Cardiomegaly, highly variable in degree, is the rule. The aortic knuckle and pulmonary trunk are inconspicuous. The pulmonary vasculature is usually normal to reduced.

Echocardiography (Fig. 62-39). The diagnosis of Ebstein anomaly is generally made with echocardiography. Apical displacement of the septal leaflet of the tricuspid valve by 8 mm/m² or greater, combined with an elongated sail-like appearance of the anterior leaflet, confirms the diagnosis. The size of the atrialized portion of the right ventricle (identified between the tricuspid annulus and the ventricular attachment of the tricuspid valve leaflets) and systolic performance of the functional right ventricle can be estimated. The degree of tricuspid regurgitation (and rarely stenosis) can be assessed. Associated defects such as ASDs, as well as the presence and direction of shunting, can also be identified (Videos 62-80 through 62-83).

Angiography. Cardiac catheterization is required mainly when concomitant coronary artery disease is suspected and to determine whether pulmonary artery pressure is elevated. When performed, selective right ventricular angiography shows the extent of tricuspid valve displacement, the size of the functional right ventricle, and configuration of its outflow tract.

Magnetic Resonance Imaging. MRI can offer insight into functional right ventricular volume and function.

Indications for Intervention

Indications for intervention include substantial cyanosis, right-sided heart failure, poor functional capacity, and perhaps the occurrence of paradoxical emboli. Recurrent supraventricular arrhythmias not controlled by medical or ablative therapy and substantial asymptomatic cardiomegaly (cardiothoracic ratio >60%) are relative indications.⁹¹

Interventional Options

When feasible, tricuspid valve repair is preferable to tricuspid valve replacement. The feasibility of tricuspid valve repair depends primarily on the experience and skill of the surgeon, as well as the adequacy of the anterior leaflet of the tricuspid valve to form a monocusp valve or a conelike structure.^{92,93} Tricuspid valve repair is possible when the edges of the anterior leaflet of the tricuspid valve are not severely tethered down to the myocardium and when the functional right ventricle is of adequate size (>35% of the total right ventricle). If the tricuspid valve is irreparable, valve replacement will be necessary, usually with a bioprosthetic tricuspid valve.⁹⁴

For “high-risk” patients (those with severe tricuspid regurgitation, an inadequate functional right ventricle [because of size or function], and/or chronic supraventricular arrhythmias), a bidirectional cavopulmonary connection can be added to reduce right ventricular preload if pulmonary artery pressure is low.⁹⁵ Occasionally a Fontan

operation may be the best option in patients with tricuspid stenosis and/or a hypoplastic right ventricle. A concomitant right atrial or biatrial maze procedure at the time of surgery should be considered in patients with chronic atrial flutter or fibrillation. If an accessory pathway is present, it should be mapped and obliterated either at the time of surgical repair or preoperatively in the catheterization laboratory. Recurrent arrhythmias after ablation do develop because of the multiple pathways and difficult anatomy and may require repeated catheter ablation.⁹⁶ Any atrial communication, if present, should be closed. In occasional patients with a resting oxygen saturation higher than 90% and exercise intolerance because of worsening hypoxemia, closure of the PFO or ASD may be indicated without addressing the tricuspid valve itself.

After satisfactory valve repair, with or without plication of the atrialized right ventricle or bidirectional cavopulmonary connection, the medium- and long-term prognosis is good.⁹⁷ Late arrhythmias can occur.⁹⁸ With valve replacement, the results are just as satisfactory. Valve re-replacement may be necessary because of a previous failing bioprosthesis or a thrombosed mechanical valve.

Reproductive Issues

In the absence of maternal cyanosis, right-sided heart failure, or arrhythmias, pregnancy is generally well tolerated.⁹⁹

Follow-Up

All patients with Ebstein anomaly should undergo regular follow-up, the frequency being dictated by the severity of the disease. Particular attention should be paid to patients with cyanosis, substantial cardiomegaly, poor right ventricular function, and recurrent atrial arrhythmias. Patients with substantial tricuspid regurgitation following tricuspid valve repair need close follow-up, as do patients with recurrent atrial arrhythmias, degenerating bioprostheses, or dysfunctional mechanical valves.

Valvular and Vascular Conditions

(see Chapters 56 and 57)

Left Ventricular Outflow Tract Lesions (Fig. 62-40)

Coarctation of the Aorta

Aortic arch obstruction may be divided into (1) localized coarctation in close proximity to a PDA or ligamentum, (2) tubular hypoplasia of some part of the aortic arch system, and (3) aortic arch interruption.

LOCALIZED AORTIC COARCTATION

Morphology. This lesion consists of a localized shelf in the posterolateral aortic wall opposite the ductus arteriosus. A neonatal manifestation is more often associated with a shelf plus a transverse aortic arch and isthmic hypoplasia, whereas with a later manifestation these areas are larger. This has important long-term implications inasmuch as persistent arch hypoplasia, even in the absence of a discrete obstruction, is one of the mechanisms of ongoing hypertension.

CLINICAL FEATURES. Coarctation occurs two to five times more commonly in males, and there is a high degree of association with gonadal dysgenesis (Turner syndrome) and a bicuspid aortic valve (≥50%). Other common associated anomalies include VSD and mitral stenosis or regurgitation. Additional lesions have an impact on outcome.

Neonates tend to have heart failure once the ductus arteriosus has closed because of a sudden increase in wall stress in the early postnatal period and undergo surgical repair a few days after diagnosis. Most infants and children with isolated coarctation are asymptomatic, with the findings of reduced femoral pulses and/or hypertension being detected during routine childhood screening. Heart failure is uncommon because the left ventricle has a chance to become hypertrophied, thus maintaining normal wall stress. Complaints of

The **upper left** image shows isolated fibromuscular obstruction; the **upper right**, stenosis secondary to a bicuspid aortic valve; the **lower left**, obstruction because of a chordal apparatus from the anterior mitral leaflet; and the **lower right**, obstruction caused by tunnel narrowing at the valve, annular, and subvalve level. AO = aorta; LA = left atrium; LV = left ventricle.

headache, cold extremities, and leg fatigue with exercise may be noted in older children and adolescents.

Presentation in adulthood again may be entirely asymptomatic and detected during routine health checks, usually because of the discovery of a murmur or unexplained hypertension. Indeed, coarctation of the aorta should be excluded in all new cases of hypertension by clinical examination of the pulses and upper and lower limb blood pressure measurement (see later). Some adolescents and adults have symptoms of functional decline in the setting of concentric left ventricular hypertrophy, or in more extreme cases, left ventricular dilation and dysfunction. Associated abnormalities include intracranial aneurysms (most commonly of the circle of Willis) in 2% to 10% and acquired intercostal artery aneurysms. One definition of *significant aortic coarctation* requires a gradient greater than 20 mm Hg across the coarctation site at angiography with or without proximal systemic hypertension. A second definition of significant aortic coarctation requires the presence of proximal hypertension along with echocardiographic or angiographic evidence of aortic coarctation. Those with extensive collateral circulation may have minimal or no pressure gradient and acquired aortic atresia.

Death in patients who do not undergo repair is most often due to heart failure (usually older than 30 years), coronary artery disease, aortic rupture or dissection, concomitant aortic valve disease, infective endarteritis or endocarditis, or cerebral hemorrhage. Of patients with Turner syndrome, 35% have aortic coarctation.

Leg claudication (pain) is rare unless concomitant abdominal aortic coarctation is present. A thorough clinical examination reveals upper limb systemic hypertension, as well as a differential systolic blood pressure of at least 10 mm Hg (brachial > popliteal artery pressure). Radial-femoral pulse delay is evident unless significant aortic regurgitation coexists. Auscultation may reveal an interscapular systolic murmur emanating from the coarctation site and a widespread crescendo-decrescendo systolic murmur throughout the chest wall from intercostal collateral arteries. Funduscopic examination can reveal “corkscrew” tortuosity of the retinal arterioles.

Laboratory Investigations

Electrocardiography. The ECG reveals left ventricular hypertrophy of various degrees, depending on the height of arterial pressure above the obstruction and the patient’s age. Coexisting right ventricular hypertrophy usually implies a complicated lesion.

Chest Radiography. The characteristic feature on the posteroanterior view is the so-called figure-3 configuration of the proximal descending thoracic aorta as a result of both prestenotic and poststenotic dilation. Rib notching (unilateral or bilateral, second to ninth ribs) is present in 50% of cases. Rib notching is unilateral if the right or left subclavian arteries arise from the aorta distal to the coarctation. Rib notching is noted as an erosion of the undersurface of a posterior rib, generally at its outer third, with a sclerotic margin.

Echocardiography. This demonstrates a posterior shelf, a well-expanded isthmus and transverse aortic arch (in most cases), and a high-velocity jet with diastolic persistence through the coarctation site. Interestingly, a slow upstroke is observed on the abdominal aortic velocity profile, in contrast to that seen in the ascending aorta.

Magnetic Resonance Imaging. MRI provides detailed information in this age group and may be performed before intervention,¹⁰⁰ particularly if balloon dilation is the treatment of choice. MRI is the best tool for postintervention imaging surveillance¹⁰¹ and has become routine in many centers.

Angiocardiology. This is reserved for delineating the coarctation at the time of balloon dilation or stent placement (Videos 62-84 through 62-86). Primary management in cases with a well-expanded isthmus and transverse aortic arch invariably involves balloon dilation and/or stent placement (Video 62-87).

INTERVENTIONAL OUTCOMES

Surgical. Surgical repair of simple coarctation usually relieves the obstruction and is associated with minimal mortality (1%). Paraplegia secondary to spinal cord ischemia is uncommon (0.4% or perhaps less¹⁰²) and may occur in patients who do not have a well-developed collateral circulation. The prevalence of recoarctation reported in the literature varies widely from 7% to 60% but is probably approximately 10%, depending on the definition used, the length of follow-up, and the age at surgery. The appropriateness of the surgical repair for a given anatomy is probably the main factor dictating the chance of recoarctation rather than the type of surgical repair itself. True aneurysm formation at the site of coarctation repair is also a well-recognized entity, with a reported incidence of between 2% and 27%. Aneurysms are particularly common after Dacron patch aortoplasty and generally occur in the native aorta opposite the patch. Late dissection at the repair site is rare, but false aneurysms, usually at the suture line, can occur. Long-term follow-up after surgical correction of coarctation of the aorta still reveals an increased incidence of premature cardiovascular disease and death, mainly attributable to prevalent associated risk factors, namely, male sex, hypertension, and hyperlipidemia.¹⁰³ The respective roles of stent therapy and surgery versus balloon dilation of aortic coarctation are becoming better defined.¹⁰⁴

Transcatheter. After balloon dilation (Fig. 62-41), aortic dissection, restenosis, and aneurysm formation at the site of coarctation have all been documented. These complications have been reduced with the now increasing if not exclusive use of primary stenting in adults with native coarctation, as well as recoarctation.¹⁰⁵ Medium-term outcomes of stent therapy in children have also been favorable.¹⁰⁶ The significance of aneurysm formation is often unknown, and longer-term data are necessary.

Previous hypertension resolves in up to 50% of patients but may recur later in life, especially if the intervention is performed at an older age.¹⁰⁷ Some of these patients may have essential hypertension, but a hemodynamic basis should be sought and blood pressure control should be attained. Systolic hypertension is also common with exercise and is not a surrogate marker for recoarctation of the aorta.^{107,108} It may be related to residual arch hypoplasia or to increased renin and catecholamine activity from residual functional abnormalities of the pre-coarctation vessels. The criteria for and significance of exertional systolic hypertension are controversial, but its presence may predict the future development of chronic hypertension.¹⁰⁸ Late cerebrovascular events can occur, notably in patients undergoing repair as adults and in those with residual hypertension. Endocarditis

**VIDEO 62-84**

This adolescent had long-segment hypoplasia of the transverse arch, which was sequentially stented with two bare metal stents.

VIDEO 62-85

This adult had severe coarctation of the aorta, which was treated with a covered stent. Note the marker pigtail catheter in the transverse arch placed from the right radial artery to monitor pressure and obtain sequential angiograms during the procedure.

VIDEO 62-86

A middle-aged man had previously been treated surgically for coarctation of the aorta with an interposition graft followed by a bypass from the ascending to the descending aorta that had become stenotic. A series of stents was used to treat the bypass conduit and the stenotic undersized interposition graft.

VIDEO 62-87

Three-dimensional rotational angiogram acquired at the time of the intervention showing the three-dimensional anatomy of the arch and lesion. The second sequence obtained after stent placement shows the anatomic details of the stent in relation to the arch structures.

The **right** image is from MRI and shows the posterior shelf and some associated transverse arch hypoplasia. **B**, Angiogram of coarctation of the aorta before and after stenting (arrows). AO = aorta.

or endarteritis can develop at the coarctation site or on intracardiac lesions; if it occurs at the coarctation site, embolic manifestations are restricted to the legs.

REPRODUCTIVE ISSUES. Patients with repaired aortic coarctation usually tolerate pregnancy well unless hemodynamically significant residual lesions are present, such as severe recoarctation or aortic stenosis from a bicuspid aortic valve. A greater propensity for the development of hypertension during pregnancy has, however, been reported.¹⁰⁹

FOLLOW-UP. All patients should have a follow-up examination every 1 to 3 years. Particular attention should be directed toward residual hypertension; heart failure; intracardiac disease such as an associated bicuspid aortic valve, which can become stenotic or regurgitant later in life; or an ascending aortopathy, which is sometimes seen in the presence of bicuspid aortic valve. Complications at the site of repair, such as restenosis and aneurysm formation, should also be sought via clinical examination, chest radiography, echocardiography, and periodic MRI or CT.¹⁰¹ Patients with a Dacron patch repair should probably undergo an MRI or spiral CT examination every 3 to 5 years or so to detect subclinical aneurysm formation. Hemoptysis from a leaking or ruptured aneurysm is a serious complication that requires immediate investigation and surgery. New or unusual headaches raise the possibility of berry aneurysms. It has long been said that coarctation patients are prone to premature coronary artery disease, but a recent study did not confirm this suspicion.¹⁰³ There is substantial evidence of a generalized arteriopathy in

coarctation patients that is not addressed by relief of the obstruction.¹¹⁰

AORTIC ARCH INTERRUPTION. Aortic arch interruption is a rare lesion but one in which surgical success has resulted in an ever-growing number of older children, adolescents, and now adults with a previous history of surgical intervention. Of importance, it is associated with DiGeorge syndrome and microdeletion of chromosome 22. Interruptions distal to the left subclavian artery (type A) occur with almost equal frequency as interruptions distal to the left common carotid artery (type B). The right subclavian artery is of variable origin but frequently arises from the descending aortic segment distal to the interruption.

Virtually all patients have associated intracardiac anomalies, typically either a VSD (80% to 90% of cases) or an aorticopulmonary window (10% to 20%). In addition, muscular left ventricular outflow tract obstruction is a common association in those with a VSD and is due to posterior deviation of the outlet septum. Other complex intracardiac malformations such as transposition of the great arteries, aorticopulmonary window, and truncus arteriosus are common.

MANAGEMENT. Primary repair initially is the main mode of treatment and includes a direct connection between the interrupted segments in conjunction with closure of the VSD. Surgical resection of the posteriorly deviated outlet septum is dealt with at the time of primary repair in some centers, whereas others address it at a later date.

OUTCOME. Medium- and long-term outcomes are reasonable,¹¹¹ but reintervention may be needed for left ventricular outflow tract obstruction and recurrent arch obstruction.

Morphology. The malformation consists of a separation—or lack of fusion—between the media of the aorta and the annulus fibrosus of the aortic valve. The receiving chamber of a right aortic sinus aortocardiac fistula is usually the right ventricle, but occasionally, when the noncoronary cusp is involved, the fistula drains into the right atrium. Five percent to 15% of aneurysms originate in the posterior or noncoronary sinus. The left aortic sinus is seldom involved. Associated anomalies are common and include a VSD, bicuspid aortic valve, and aortic coarctation.

CLINICAL FEATURES. The deficiency of the aortic media appears to be congenital. Reports in infants are exceedingly rare and are infrequent in children because progressive aneurysmal dilation of the weakened area develops but may not be recognized until the third or fourth decade of life, when rupture into a cardiac chamber occurs. A congenital aneurysm of an aortic sinus of Valsalva, particularly the right coronary sinus, is an uncommon anomaly that occurs three times more often in males. An unruptured aneurysm does not usually produce a hemodynamic abnormality. Rarely, myocardial ischemia may be caused by coronary arterial compression. Rupture is frequently of abrupt onset, causes chest pain, and creates continuous arteriovenous shunting and acute volume loading of both the right- and left-sided heart chambers, which promptly results in heart failure. An additional complication is infective endocarditis, which may originate either on the edges of the aneurysm or on areas in the right side of the heart that are traumatized by the jetlike stream of blood flowing through the fistula.

The presence of this anomaly should be suspected in patients with a combination of chest pain of sudden onset; resting or exertional

dyspnea; bounding pulses; and a loud, superficial, continuous murmur accentuated in diastole when the fistula opens into the right ventricle, as well as a thrill along the right or left lower sternal border.

Laboratory Investigations

Electrocardiography. The ECG may show biventricular hypertrophy, or the findings may be normal.

Chest Radiography. This may demonstrate generalized cardiomegaly and usually heart failure after the fistula develops.

Echocardiography. Studies based on two-dimensional and pulsed Doppler echocardiography may detect the walls of the aneurysm and disturbed flow within the aneurysm or at the site of perforation. TEE may provide more precise information than obtained with the trans-thoracic approach.

Cardiac Catheterization. This reveals a left-to-right shunt at the ventricular or, less commonly, the atrial level; the diagnosis may be established definitively by retrograde thoracic aortography.

MANAGEMENT OPTIONS AND OUTCOMES. Preoperative medical management consists of measures to relieve cardiac failure and treat coexistent arrhythmias or endocarditis, when present. At surgery the aneurysm is closed and amputated, and the aortic wall is reunited with the heart, either by direct suture or with a prosthesis. All effort should be made to preserve the aortic valve in children because patch closure of the defect combined with prosthetic valve replacement greatly increases the risk associated with surgery in small patients. Late results of surgical repair have been excellent.¹¹² Device closure of the ruptured aneurysm has also been attempted.

Vascular Rings

Morphology. The term *vascular ring* is used for aortic arch or pulmonary artery malformations that exhibit an abnormal relationship with the esophagus and trachea, and they often cause dysphagia and/or respiratory symptoms.

Double Aortic Arch (Fig. e62-6). The most common vascular ring is produced by a double aortic arch in which both the right and left fourth embryonic aortic arches persist. In the most common type of double aortic arch, a left ligamentum arteriosum or occasionally a ductus arteriosus is present. Although both arches may be patent at the time of diagnosis, invariably the left arch distal to the left subclavian artery is atretic and connected to the descending aorta by a fibrous remnant that completes the ring. In the setting in which both arches are patent, the right arch is typically larger than the left. This usually occurs as an isolated lesion, with the respiratory symptoms being caused by tracheal compression and frequently associated laryngomalacia, generally in neonates and young infants.

Right Aortic Arch. A right aortic arch with a left ductus or ligamentum arteriosum connecting the left pulmonary artery and the upper part of the descending aorta is the next most important vascular ring seen. Although all patients with this lesion have a vascular ring, not all are symptomatic. Indeed, patients who are symptomatic usually have an associated diverticulum of Kommerell. This is a large outpouching at the distal takeoff of the left subclavian artery from the descending aorta. It is the combination of the diverticulum and the ring that causes the airway compression.

Anomalous Origin of a Right Subclavian Artery. An anomalous origin of a right subclavian artery is one of the most common abnormalities of the aortic arch. Although the aberrant right subclavian artery runs posterior to the esophagus, it does not form a vascular ring unless an associated right-sided ductus or ligamentum is present to complete the ring. During adulthood approximately 5% of patients with an aberrant right subclavian artery (and a left ductus) have symptoms because of rigidity of the aberrant vessel.

Retrosophageal Descending Aorta. With this rarer but more problematic type of vascular ring there may be either an ascending left and descending right aorta or an ascending right and descending left aorta. The retrosophageal component of the descending aorta, in conjunction with the left- or right-sided ligamentum, causes the tracheal compression.

Pulmonary Artery Sling. This condition is usually caused by the left pulmonary artery arising from the right pulmonary artery and running posterior to the trachea but anterior to the esophagus. It is usually seen in isolation and is associated with significant hypoplasia of the bronchial tree, which is the predominant cause of the airway symptoms.

CLINICAL FEATURES. The symptoms produced by vascular rings depend on the tightness of anatomic constriction of the trachea and esophagus and consist principally of respiratory difficulties, including stridor, cyanosis (especially with feeding), and dysphagia. Not all patients with a vascular ring are symptomatic, and cases with an aberrant left subclavian artery are frequently detected at the time of evaluation for associated CHD. Although most patients with a true ring and some airway compression are initially seen early in life, others are evaluated later for dysphagia, and some escape diagnosis forever.

Laboratory Investigations

Electrocardiography. Findings on the ECG appear normal unless associated cardiovascular anomalies are present.

Chest Radiography. If there is evidence of a right aortic arch in a symptomatic patient, a vascular ring should be suspected. In some cases evidence of some airway narrowing is present. A barium esophagogram is a useful screening procedure. Prominent posterior indentation of the esophagus is observed in many of the common vascular ring arrangements, although a pulmonary artery vascular sling produces an anterior indentation.

Echocardiography. Even though echocardiography is a sensitive tool for evaluating the laterality of the aortic arch, including a detailed assessment of the associated brachiocephalic vessels, MRI is rapidly becoming the preferred mode of investigation before intervention. This technique has the added advantage that it is possible to image the more posterior structures that run behind the esophagus and trachea. In general, if there is normal branching of the innominate artery to the right for a left aortic arch and to the left for a right one, along with the correct "sidedness" of the descending aorta, a vascular ring can be excluded. *Most patients with a double aortic arch* have a dominant right arch, with the descending aorta appearing to dip posteriorly as it runs behind the esophagus. A patent ductus or ligamentum can generally be identified by echocardiography. When both arches are patent, a frontal plane sweep from inferior to superior demonstrates both patent arches, as well as their brachiocephalic vessels. *A right aortic arch with an aberrant left subclavian artery* is suspected when it is not possible to identify normal branching of the left-sided innominate artery. *A retrosophageal descending aorta* should be suspected when the ascending aorta and its brachiocephalic arteries are readily identified but it is difficult to identify the descending aorta as it traverses behind the esophagus. *A left pulmonary artery sling* is suspected when the normal branching pattern of the pulmonary arteries cannot be identified. In this setting color Doppler permits identification of the left pulmonary artery as it arises from the right pulmonary artery and runs in a posterior and leftward direction.

Magnetic Resonance Imaging and Computed Tomography. MRI and CT play a major role in the evaluation of patients with a vascular ring. In fact, MRI has become the gold standard for evaluation of the aorta and its branches. The only disadvantage in infants is that general anesthesia is often required to achieve a successful examination. On the other hand, spiral CT is a technique that is fast and provides better definition of the affected airways. This latter technique is particularly valuable for patients with a pulmonary artery sling, in whom the vascular ring plays a secondary role to the airway abnormalities. The advantages of these techniques are that unlike echocardiography, they permit precise assessment of the more posterior vascular structures and their relationships to the esophagus and airways. These techniques are particularly valuable in evaluating more complex forms, such as a retrosophageal descending aorta.

MANAGEMENT OPTIONS AND OUTCOMES. The severity of symptoms and the anatomy of the malformation are the most important factors in determining treatment. Patients, particularly infants, with respiratory obstruction require prompt surgical intervention. A left thoracotomy is the surgical approach in most patients with a vascular ring. Operative repair of a double aortic arch requires division of the minor arch (usually the left) and the ligamentum. Patients with a right aortic arch and a left ductus or ligamentum arteriosum require division of the ductus or ligamentum and/or ligation and division of the left subclavian artery, which is the posterior component of the ring. Video-assisted thoracoscopy holds promise as an alternative to open thoracotomy for management. In patients with a pulmonary artery vascular sling, surgery consists of detachment of the left pulmonary artery at its origin and anastomosis to the

FIGURE e62-6 MRI of a patient with a double aortic arch, a dominant posterior right arch, and a hypoplastic but patent left aortic arch.

main pulmonary artery directly or by way of a conduit with its proximal end brought anterior to the trachea. The addition of tracheal narrowing requiring surgical intervention adds to the mortality in this group of patients, as does its association with intracardiac malformations.

Congenital Aortic Valve Stenosis

GENERAL CONSIDERATIONS. Congenital aortic valve stenosis is a relatively common anomaly. It occurs much more frequently in males, with a sex ratio of 4:1. Associated cardiovascular anomalies have been noted in up to 20% of patients. PDA and coarctation of the aorta occur most frequently with aortic valve stenosis; all three of these lesions may coexist.

Morphology. The basic malformation consists of thickening of valve tissue with various degrees of commissural fusion. Despite fusion of the leaflet, in most cases three sinuses are still present. The valve is most commonly bicuspid, which in most cases is the result of fusion of two leaflets rather than actual absence of one of the leaflets. The fusion usually involves the two coronary sinuses or the right and noncoronary sinuses. In some patients (usually newborns) the stenotic aortic valve is unicuspid and dome shaped, with no or one lateral attachment to the aorta at the level of the orifice. In infants and young children with severe aortic stenosis, the aortic valve annulus may be relatively underdeveloped.

CLINICAL FEATURES. For cardiologists managing adults, the relevance of a past history of a newborn manifestation of aortic valve stenosis is that this population invariably does not have isolated aortic valve pathology. It is common for them to have associated endocardial fibroelastosis, as well as abnormalities of their mitral valves. These patients are often initially seen in heart failure, are generally managed with balloon dilation at that time, and invariably have ongoing aortic valve issues in the form of residual stenosis and/or regurgitation. Many require reintervention in their younger years in the form of further balloon dilation or aortic valve replacement. These patients are surviving into adolescence and young adulthood and will have more ongoing issues than those initially encountered at a later date. In older children, adolescents, and adults the diagnosis is usually made following detection of a murmur; symptomatic functional decline, presyncope, and syncope are rarely the initial features. Natural history studies performed several years ago demonstrated that more rapid progression of aortic valve stenosis is more likely to take place within the first 2 years of life, following which the rate of progressive obstruction is more uniform.

In general, affected children are asymptomatic, with normal peripheral pulses if the stenosis is less severe and low-volume, slowly rising pulses when it progresses. Exercise-related fatigue and chest pain are rare complaints and occur only when the stenosis is severe. With severe stenosis there is a systolic thrill in the same area that can also be felt in the suprasternal notch and carotid arteries. Beyond the newborn period, an ejection click usually occurs at the apex and precedes the murmur. The second heart sound is generally normal in children. An ejection systolic murmur is heard along the left sternal border, with radiation into the right infraclavicular area. Associated aortic regurgitation may be heard.

Laboratory Investigations

Electrocardiography. Left ventricular hypertrophy with or without strain is the hallmark feature.

Chest Radiography. Overall heart size is normal unless left ventricular remodeling is severe or important associated valvar regurgitation is present.

Echocardiography. Two-dimensional echocardiography provides detailed information about the morphology of the valve, left ventricular function, and the presence of associated left-sided lesions. Doppler echocardiography can be used to determine the severity of stenosis and the presence or absence of associated aortic regurgitation. Doppler provides instantaneous peak gradients that are higher than the peak-to-peak gradients determined via cardiac catheterization. The importance of this lies in the fact that natural history studies and

clinical decision making have thus far been based on peak-to-peak catheterization gradients in infants, children, and adolescents. Valve areas are not usually calculated in this age group because of the lack of good data supporting their use in pediatric patients. Mean gradients as derived from Doppler examination and catheterization correlate closely, but again, no data support their use in clinical decision making. Some data can be used to convert the Doppler-derived mean gradients to peak-to-peak gradients, with the addition of pulse pressure as obtained from blood pressure measurements. Whatever absolute number is chosen to work with, the additional finding of left ventricular hypertrophy on electrocardiography and echocardiography provides supportive data regarding timing for intervention. Pediatric cardiologists generally agree that a peak-to-peak gradient of 60 mm Hg or greater probably warrants intervention even in the absence of symptoms, although clearly the thresholds for intervention are different from those in adults.

Cardiac Catheterization. Cardiac catheterization is now rarely used to establish the site and severity of obstruction to left ventricular outflow. Instead, catheterization is undertaken when therapeutic interventional balloon aortic valvuloplasty is indicated.

MANAGEMENT OPTIONS. In this era, balloon dilation has almost completely replaced primary surgical valvotomy in children (Video 62-88). Balloon valvuloplasty retains a place in the management of adolescents and young adults, but with increasing age it becomes a less attractive option and is rarely successful in those with sclerotic and calcified valves at any age. A 2012 paper compared the results of surgical and balloon therapy for congenital aortic stenosis.¹¹³ Another described the midterm outcomes of the Ross procedure in infants.¹¹⁴

FOLLOW-UP. Follow-up studies indicate that aortic valvotomy is a safe and effective means of palliative treatment that affords excellent relief of symptoms. Aortic insufficiency can occasionally be progressive and require valve replacement. Moreover, after commissurotomy the valve leaflets remain somewhat deformed, and further degenerative changes, including calcification, will probably lead to significant stenosis in later years. Thus prosthetic aortic valve replacement is required in approximately 35% of patients within 15 to 20 years of the original operation. In children and adolescents requiring aortic valve replacement, surgical options include replacement with a mechanical aortic valve, an aortic homograft, or a pulmonary autograft in the aortic position. Accumulating evidence is showing that a pulmonary autograft may ultimately be preferable to an aortic homograft. In a pulmonary autograft operation, called the *Ross procedure*, the patient's pulmonary valve is removed and used to replace the diseased aortic valve, and the right ventricular outflow tract is reconstructed with a pulmonary valve homograft. This approach appears to confer a survival advantage in the younger age group, in whom repeated mechanical valve replacement is associated with increased mortality. Despite this advantage, caution is necessary when applied to patients with a bicuspid aortic valve and aortic regurgitation because of the associated aortic root dilation, which is inherent with this lesion and may complicate the long-term durability of the Ross procedure. This surgical approach can be applied from neonatal through adult life. Neither homografts nor autografts require anticoagulation.

Subaortic Stenosis

Morphology

Discrete Fibromuscular. This lesion consists of a ridge or fibrous ring encircling the left ventricular outflow tract at varying distances from the aortic valve. The subvalvular fibrous process usually extends onto the aortic valve cusps and almost always makes contact with the ventricular aspect of the anterior mitral leaflet at its base. In cases with fibrous discontinuity between the mitral and aortic valves it forms more of a tunnel obstruction.

Focal Muscular. Rarely, no fibrous element is present, but rather a focal muscular obstruction on the crest of the interventricular septum, which differs from typical cases with hypertrophic cardiomyopathy.

Hypoplasia of the Left Ventricular Outflow Tract. In some cases, valvular and subvalvular aortic stenoses coexist with hypoplasia of the aortic valve annulus and thickened valve leaflets and produce a tunnel-like narrowing of the left ventricular outflow tract. Additional findings often include a small ascending aorta.

**VIDEO 62-88**

This 3-day-old has critical (duct-dependent) aortic valve stenosis. Balloon dilation is performed via a transatrial technique to (1) avoid potential arterial compromise and (2) ensure that the balloon is through the hemodynamic orifice. Note in the last sequence the reversal of ductal flow from right to left and left to right, coincident with improved cardiac output.

Discrete Subaortic Stenosis and Ventricular Septal Defect. This combination is frequently encountered in the pediatric age group, with the fibromuscular component often being absent at initial echocardiographic evaluation. The association should be suspected in VSDs with some associated anterior malalignment of the aorta and a more acute aortoseptal angle. Subpulmonary stenosis frequently develops in these hearts. In a different subset of patients with aortic arch interruption and a VSD, muscular subaortic stenosis is present because of posterior deviation of the infundibular septum.

Complex Subaortic Stenosis. Various anatomic lesions other than a discrete ridge may produce subaortic stenosis. Among these are abnormal adherence of the anterior leaflet of the mitral valve to the septum and the presence of accessory endocardial cushion tissue in the left ventricular outflow tract. These lesions are frequently associated with a “cleft in the anterior mitral valve leaflet,” which is to be differentiated from that seen in an AV septal defect. These types of obstruction are more commonly present in patients with abnormalities of the ventriculoarterial connection in association with a VSD (e.g., double-outlet right ventricle, transposition, VSD).

CLINICAL FEATURES. These types of obstruction are usually identified as secondary lesions in patients with associated VSDs, with or without abnormalities in the ventriculoarterial connections or aortic arch obstruction. In general, the substrate for left ventricular outflow tract obstruction is present, although in some cases actual physiologic obstruction is absent. In other instances patients with a systolic murmur are referred for evaluation. In patients with a gradient across the left ventricular outflow tract, an ejection systolic murmur is heard along the lower left sternal border together with the absence of an ejection click.

Laboratory Investigations

Electrocardiography. In those with associated defects, the ECG reflects the major abnormality rather than the associated left ventricular outflow tract obstruction. With isolated forms of left ventricular outflow tract obstruction, left ventricular hypertrophy may be present when the obstruction is significant.

Chest Radiography. This is not usually helpful in these cases.

Echocardiography (Videos 62-89 through 62-91). Echocardiography is the standard diagnostic tool for subaortic stenosis. Not only can it permit accurate delineation of the mechanisms of obstruction, but it also provides detailed data regarding associated lesions. In all forms the parasternal long-axis view is key to providing an accurate diagnosis. The presence of mitral-aortic discontinuity, the relationship of a fibromuscular ridge to the aortic valve, the presence of accessory obstructive tissue, and the dimensions of the aortic annulus and root are all well imaged with this view. In addition, color flow mapping permits the identification of associated aortic valve regurgitation and provides hemodynamic evidence of the site of onset of the obstruction. Extension of a fibromuscular ridge onto the anterior mitral leaflet is best appreciated on the apical five-chamber view. This view also provides the best site for pulsed- or continuous-wave Doppler assessment of the maximum gradient across the left ventricular outflow tract. In older patients TEE plays an important role in delineating the pathology. Real-time three-dimensional echocardiography provides additional information, particularly in those with complex mechanisms of left ventricular outflow tract obstruction (Fig. e62-7).

Cardiac Catheterization. This technique is no longer of importance in evaluating this lesion. Balloon dilation of discrete fibrous ridges has recently been reported from one center to have had favorable long-term outcomes.¹¹⁵

Magnetic Resonance Imaging. In general, MRI is unnecessary unless there are problems obtaining the needed information with echocardiography.

INTERVENTIONAL OPTIONS. Surgical intervention is indicated either at the time of repair of the underlying primary lesion or in patients with discrete obstruction when the obstruction is severe enough to raise concern.

DISCRETE SUBAORTIC STENOSIS (FIBROUS AND MUSCULAR). The rate of progression is varied and may be slow. In general, the approach to the latter group has been to intervene when the mean echocardiographic gradient across the left ventricular outflow tract is greater than 30 mm Hg to avoid future aortic leaflet damage. Surgery involves fibromyectomy, with care taken to avoid damage to the aortic valve or to create an iatrogenic VSD. Subaortic stenosis can

recur and requires reoperation in up to 20% of cases.¹¹⁶ In some patients recurrence is in the form of a fibrous ridge, whereas others have acquired pathology of the aortic valve in the form of stenosis and/or regurgitation. Reoperation may involve just repeated resection of a recurrent fibrous ridge, or it may involve surgery on the aortic valve in patients with significant aortic regurgitation.

COMPLEX FORMS OF LEFT VENTRICULAR OUTFLOW TRACT OBSTRUCTION WITH AN INTACT VENTRICULAR SEPTUM. In patients with an intact ventricular septum the indications for intervention are similar to those for discrete obstruction. The difference lies in the fact that the surgical approach must be modified according to the underlying pathology and that reoperation is more frequent.¹¹⁷ Resection of any fibromuscular component or accessory tissue (provided that it is not a primary support mechanism for the mitral valve), a valve-sparing Konno operation, and in patients with a hypoplastic aortic annulus, a classic Konno procedure with aortic valve replacement are the potential surgical options.

LEFT VENTRICULAR OUTFLOW TRACT OBSTRUCTION AND COMPLEX FORMS OF CONGENITAL HEART DISEASE. In general, surgery on the left ventricular outflow tract is part of general repair of the lesion and is not dependent on the precise degree of obstruction across this site.

OUTCOMES. Immediate complications related to surgery include complete AV block, inadvertent creation of a VSD, or mitral regurgitation from intraoperative damage to the mitral valve apparatus. Long-term complications include recurrence of fibromuscular subvalvular left ventricular outflow tract obstruction (up to 20%), clinically important aortic regurgitation, and valvular aortic stenosis (especially in the context of a bicuspid aortic valve or aortic coarctation).^{118,119} In some patients with predominant acquired aortic valve stenosis, balloon dilation has been the treatment of choice.

FOLLOW-UP. Particular attention should be paid to patients with residual or recurrent subaortic stenosis or those with an associated bicuspid aortic valve or important aortic regurgitation because they are most likely to eventually require surgery. Reoperation is more likely in patients with complex forms of obstruction, younger age at surgery, and incomplete relief of obstruction at the initial procedure. Patients with bioprosthetic aortic valves in the aortic position (following the Konno procedure) or the pulmonary position (following the Ross-Konno procedure) need close follow-up. Endocarditis prophylaxis should be used for prosthetic valves.

Supravalvular Aortic Stenosis

Morphology. Three anatomic types of supravalvular aortic stenosis are recognized, although some patients may have findings of more than one type. Most common is the hourglass type, in which marked thickening and disorganization of the aortic media produce a constricting annular ridge at the superior margin of the sinuses of Valsalva. The membranous type is the result of a fibrous or fibromuscular semicircular diaphragm with a small central opening stretched across the lumen of the aorta. Diffuse hypoplasia of the ascending aorta characterizes the third type.

Because the coronary arteries arise proximal to the site of outflow obstruction in supravalvular aortic stenosis, they are subjected to the elevated pressure that exists within the left ventricle. These vessels are often dilated and tortuous, and premature coronary arteriosclerosis has been described. Moreover, if the free edges of some or all of the aortic cusps adhere to the site of supravalvular stenosis, coronary artery inflow may be compromised. The left ventricle may have a “ballerina foot” configuration, which can result in muscular left ventricular outflow tract obstruction, particularly when associated with significant supravalvular obstruction.

CLINICAL FEATURES. The clinical picture of supravalvular obstruction differs in major respects from that observed in the other forms of aortic stenosis. Chief among these differences is the association of supravalvular aortic stenosis with idiopathic infantile hypercalcemia, a disease that occurs in the first years of life and can be associated with deranged vitamin D metabolism.

Williams Syndrome. The designation *supravalvular aortic stenosis syndrome*, *Williams syndrome*, or *Williams-Beuren syndrome* has been applied to the distinctive picture produced by coexistence of the

FIGURE e62-7 These images demonstrate fibromuscular subaortic stenosis as seen on three-dimensional echocardiography. The **upper** two panels show the aortic valve as seen by the surgeon, whereas the **middle** image is just distal to that and shows the crescent-shaped subaortic membrane. The **lower** image shows the fibromuscular ridge as seen on two-dimensional TEE. RV = right ventricle; SUB AS = subaortic stenosis.

Fibromuscular subaortic stenosis. This TEE loop shows the tunnel nature of the left ventricular outflow tract obstruction caused by hypertrophy of the septum and extension onto the area of the mitral-aortic junction.

VIDEO 62-91

Fibromuscular subaortic stenosis. This real-time three-dimensional image loop shows the extent of the fibromuscular subaortic ridge as seen on the surgical view through the aortic valve. Note the button hole appearance of the orifice showing that the ridge extends all the way around the left ventricular outflow tract.

cardiac features in the setting of a multisystem disorder. Beyond infancy in these patients, a challenge with vitamin D- or calcium-loading tests unmasks abnormalities in the regulation of circulating 25-hydroxyvitamin D. Infants with Williams syndrome often exhibit feeding difficulties, failure to thrive, and gastrointestinal problems in the form of vomiting, constipation, and colic. The entire spectrum of clinical manifestations includes auditory hyperacusis, inguinal hernia, a hoarse voice, and a typical personality that is outgoing and engaging. Other manifestations of this syndrome include intellectual impairment, "elfin facies," narrowing of peripheral systemic and pulmonary arteries, strabismus, and abnormalities in dental development consisting of microdontia, enamel hypoplasia, and malocclusion.

Many medical conditions can complicate the course of Williams syndrome, including systemic hypertension, gastrointestinal problems, and urinary tract abnormalities. In older children or adults, progressive joint limitation and hypertonia may become a problem. Adult patients are usually handicapped by their developmental disabilities.

Williams syndrome was previously considered to be nonfamilial; however, a number of families in which parent-to-child transmission of Williams syndrome has occurred have now been identified. All these families have a parent and child affected with Williams syndrome, including one instance of male-to-male transmission. This supports autosomal dominant inheritance as the probable pattern, with most cases of Williams syndrome probably occurring as the result of a new mutation. New information indicates that a genetic defect for supravalvular aortic stenosis is located in the same chromosomal subunit as elastin on chromosome 7q11.23. Elastin is an important component of the arterial wall, but precisely how mutations in elastin genes cause the phenotypes of supravalvular aortic stenosis is not known.

Familial Autosomal Dominant Manifestation. Occasionally, the aortic anomaly and peripheral pulmonary arterial stenosis are also found in familial and sporadic forms not associated with the other features of the syndrome. Affected patients have normal intelligence and are normal in facial appearance. Genetic studies suggest that when the anomaly is familial, it is transmitted as autosomal dominant with variable expression. Some family members may have peripheral pulmonary stenosis either as an isolated lesion or in combination with the supravalvular aortic anomaly.

Clinical Features. Patients with Williams syndrome are intellectually challenged (Fig. e62-8). The typical appearance is similar to that of the elfin facies observed in the severe form of idiopathic infantile hypercalcemia and is characterized by a high prominent forehead, stellate or lacy iris patterns, epicanthal folds, underdeveloped bridge of the nose and mandible, overhanging upper lip, strabismus, and anomalies in dentition. Recognition of this distinctive appearance, even in infancy, should alert the physician to the possibility of underlying multisystem disease. In addition, a positive family history in a patient with a normal appearance and clinical signs suggesting left ventricular outflow obstruction should lead to suspicion of either supravalvular aortic stenosis or hypertrophic obstructive cardiomyopathy.

Previous studies of the natural history of the principal vascular lesions in these patients—supravalvular aortic stenosis and peripheral pulmonary artery stenosis—indicate that the aortic lesion is usually progressive, with an increase in the intensity of obstruction often related to poor growth of the ascending aorta. This has recently been questioned in a longitudinal single-center study in which those with smaller gradients at initial evaluation appeared to have evidence of regression of their stenosis.¹²⁰ Those with pulmonary branch stenosis, regardless of whether it is associated with the aortic lesion, tend to show no change or a reduction in right ventricular pressure with time.

With few exceptions, the major *physical findings* resemble those observed in patients with aortic valve stenosis. Among these exceptions are accentuation of aortic valve closure because of elevated pressure in the aorta proximal to the stenosis, an absent ejection click, and the especially prominent transmission of a thrill and murmur into the jugular notch and along the carotid vessels. The narrowing of the peripheral pulmonary arteries may produce a late systolic or continuous murmur heard best in the lung fields and is generally accentuated by inspiration. Another hallmark of supravalvular aortic stenosis is that systolic pressure in the right arm is usually higher than that in the left arm. This pulse disparity may be related to the tendency of a jet stream to adhere to a vessel wall (Coanda effect) and selective streaming of blood into the innominate artery.

Laboratory Investigations

Electrocardiography. The ECG generally reveals left ventricular hypertrophy when the obstruction is severe. Biventricular or even right ventricular hypertrophy may be found if the peripheral pulmonary arteries are significantly narrowed.

Chest Radiography. In contrast to valvular and discrete subvalvular aortic stenosis, dilation of the ascending aorta is absent.

Echocardiography. This is a valuable technique for localizing the site of obstruction to the supravalvular area. Most often the sinuses of Valsalva are dilated, and the ascending aorta and arch appear to be small or of normal size. The diameter of the aortic annulus is always greater than that of the sinotubular junction. Doppler examination is used to determine the location of obstruction but generally overestimates the gradient when compared with that obtained at cardiac catheterization. This results from the obstruction being lengthy, and the Doppler gradient being overestimated because of the phenomena of pressure recovery.

Angiocardiography. In most cases angiocardiography is necessary to define an accurate hemodynamic gradient across the left ventricular outflow tract, as well as to determine the status of the coronary arteries. Usually it also involves assessment of the branch pulmonary arteries, as well as the brachiocephalic, renal, and mesenteric arteries, all of which can be stenotic. Because of the nature of the anatomic defect, transcatheter balloon angioplasty, with or without stenting, is not an effective treatment option.

INTERVENTIONAL OPTIONS AND OUTCOMES. Surgical intervention for supravalvular aortic stenosis has been successful in most patients with good medium- and long-term results.¹²¹ A variety of surgical procedures may be performed, all of which are tailored to the type of pathology. Application of a Y patch, resection with end-to-end anastomosis, and a Ross procedure are the main techniques used. Additional procedures, including coronary bypass of ostial stenosis, aortic valvuloplasty, and subaortic resection, may be necessary in some cases.

The cardiac prognosis is good, with some patients requiring further surgery for recurrent supravalvular stenosis.¹²² Because peripheral pulmonary artery stenosis tends to improve with time, there is a reluctance to attempt intervention, either surgical or via balloon angioplasty. Long-term behavioral and intellectual problems persist.

Congenital Mitral Valve Anomalies

Congenital Mitral Stenosis

Morphology. Anatomic types of mitral stenosis include a parachute deformity of the valve in which shortened chordae tendineae converge and insert into a single large papillary muscle (see Video 62-6), thickened leaflets with shortening and fusion of the chordae tendineae, an anomalous arcade of obstructing papillary muscles, accessory mitral valve tissue, and a supravalvar circumferential ridge or "ring" of connective tissue arising at the base of the atrial aspect of the mitral leaflets. Associated cardiac defects are common and include endocardial fibroelastosis, coarctation of the aorta, PDA, and left ventricular outflow tract obstruction (Videos 62-92 and 62-93). An association between persistence of the left superior vena cava and obstructive left-sided lesions also exists.

CLINICAL FEATURES. In most cases the findings are incidental at the time of evaluation of another left-sided obstructive lesion, such as coarctation of the aorta or aortic valve stenosis. The classic auscultatory findings seen with rheumatic mitral valve stenosis are often absent in the congenital form. Typical findings include a normal S₁, a mid-diastolic murmur with or without some presystolic accentuation, and no opening snap.

Laboratory Investigations

Electrocardiography. In milder forms, findings on the ECG are usually normal, or there may be left atrial overload, with or without right ventricular hypertrophy because of the associated pulmonary hypertension.

Chest Radiography. Findings are normal in milder forms, with evidence of pulmonary edema in patients with more severe obstruction.

Echocardiography. Two-dimensional echocardiography and more recently three-dimensional echocardiography, combined with Doppler studies, usually provide a complete analysis of the anatomy and function of congenital mitral stenosis. The status of the papillary muscles is best appreciated on the precordial short-axis view. If two papillary muscles are present, they are generally closer together than occurs in a normal heart. A precordial long-axis view permits identification of a supravalvular mitral ring, as well as the degree of mobility of the valve

FIGURE e62-8 Typical elfin facies in three patients with supraventricular aortic stenosis. (From Friedman WF, Kirkpatrick SE: Congenital aortic stenosis. VIDEO 62-92

Congenital mitral valve and subaortic stenosis. This TEE image shows a loop demonstrating a stenotic mitral valve. Note that the leaflets are thickened and that there is a subannular ridge of tissue. The interventricular septum is also hypertrophied.

VIDEO 62-93

Congenital mitral valve and subaortic stenosis. This loop shows the color jet through the orifice of the mitral valve, as well as subaortic stenosis, which is located in the subvalve region.

leaflets. Color flow Doppler allows identification of the level of the obstruction, as well as the presence of mitral valve regurgitation. Pulsed- or continuous-wave Doppler provides an accurate assessment of the mean gradient across the mitral valve. The advantage of the pressure half-time lies in the fact that it is independent of cardiac output, unlike the mean gradient across the mitral valve. Because of more rapid heart rates in children, the pressure half-time is of less value.

INTERVENTIONAL OPTIONS AND OUTCOMES. In asymptomatic cases, clinical and echocardiographic follow-up is all that is necessary. The presence of a single papillary muscle in itself does not predict progressive stenosis. If pulmonary hypertension or symptoms start to develop, surgical intervention is usually indicated. Mitral valve balloon dilation is not as successful as it is for rheumatic mitral valve stenosis. Surgery usually involves removing a supramitral ring when present and splitting both papillary muscles and fused chordal apparatus in those with the more common forms of congenital mitral stenosis.^{123,124} In general, surgical intervention provides temporary relief, with many operated patients requiring valve replacement later in life.^{125,126}

Congenital Mitral Regurgitation

Morphology

Isolated Congenital Mitral Valve Regurgitation. This is usually either due to an isolated cleft of the anterior mitral valve leaflet or is the result of leaflet dysplasia. In the latter cases there is evidence of shortened chordae in conjunction with dysplastic valve leaflets. In those with an isolated mitral valve cleft, the deficiency in the anterior mitral leaflet points toward the left ventricular outflow tract, unlike cases with an AV septal defect. In general, the larger the cleft in the anterior mitral leaflet, the greater the degree of regurgitation.

In cases with a *dysplastic* mitral valve the chordal apparatus is shortened with varying degrees of dysplasia of the leaflets. Other anatomic lesions such as mitral valve arcade resulting in regurgitation are usually part of a more generalized abnormality of the left side of the heart.

COMPLEX CONGENITAL MITRAL VALVE REGURGITATION. This is seen more frequently in association with abnormalities of the ventriculoarterial connection, such as a double-outlet right ventricle, transposition and VSD, and corrected transposition. In the first two there is often a cleft in the anterior mitral valve leaflet with some chordal support apparatus that renders the valve less regurgitant than in patients with an isolated cleft. In cc-TGA the morphologic mitral valve may have an associated cleft, be dysplastic, or have multiple papillary muscles, all of which increase the tendency for it to be regurgitant.

CLINICAL FEATURES. The presence of symptoms is related to the severity of the regurgitation in cases in which the pathology is isolated to the valve. Exercise intolerance and a pansystolic murmur at the apex, with or without a mid-diastolic murmur, are the cardinal clinical features.

Laboratory Investigations

Electrocardiography. Findings on the ECG are either normal or demonstrate left atrial and left ventricular hypertrophy.

Chest Radiography. This demonstrates cardiomegaly predominantly involving the left ventricle and atrium.

Echocardiography. Doppler and two-dimensional echocardiography provide an accurate evaluation of the mechanisms and degree of valvular regurgitation. The cleft in the anterior mitral valve leaflet is best seen on the precordial short-axis view, pointed toward the left ventricular outflow tract (Videos 62I-94 through 62-99). Patients with a dysplastic mitral valve lack mobility of the valve leaflets and have shortened chordae. Color Doppler interrogation helps in locating the site of regurgitation. The severity of regurgitation is assessed in standard fashion. Three-dimensional echocardiography permits a comprehensive evaluation of the mechanisms of regurgitation, with additional information being obtained regarding commissural length, leaflet area, and sites of regurgitation from color flow Doppler.

Angiocardiology and Magnetic Resonance Imaging. These procedures are seldom helpful in management planning.

INTERVENTIONAL OPTIONS AND OUTCOMES. The need for intervention depends on the severity of regurgitation and its impact

on left ventricular function. Surgery should not be delayed until patients become symptomatic. Surgery involves suture of an isolated cleft, with or without associated commissuroplasties. In patients with a dysplastic mitral valve, leaflet extension in conjunction with an annuloplasty and commissuroplasty usually results in effective control of the regurgitation in the short and medium term.¹²⁷ Nonetheless, many of these patients end up with a mitral valve replacement at some stage in the future. Attempted surgical repair, rather than replacement, is important in the pediatric age group because it permits temporary relief that allows the child to grow so that future surgery can be done when the mitral annulus is larger. When required, mitral valve replacement has had good short- and medium-term outcomes in cases in which repair is not possible.

Right Ventricular Outflow Tract Lesions

Peripheral Pulmonary Artery Stenosis (Fig. e62-9)

This term applies to patients with both peripheral pulmonary artery stenosis and an intact ventricular septum. It excludes those with an associated VSD, which is dealt with in the sections on tetralogy of Fallot and pulmonary atresia with a VSD. Also excluded is Noonan syndrome, which is dealt with in the subsequent section on pulmonary valve stenosis.

Cause

Rubella Syndrome. The most important cause of significant pulmonary artery stenoses producing symptoms in newborns used to be intrauterine rubella infection. Other cardiovascular malformations commonly found in association with congenital rubella include PDA, pulmonary valve stenosis, and ASD. Generalized systemic arterial stenotic lesions may also be a feature of rubella embryopathy, which may involve large- and medium-sized vessels such as the aorta and coronary, cerebral, mesenteric, and renal arteries. Cardiovascular lesions are but one manifestation of intrauterine rubella infection; cataracts, microphthalmos, deafness, thrombocytopenia, hepatitis, and blood dyscrasias are also common. The clinical picture in infants with rubella syndrome depends on the severity of the cardiovascular lesions and the associated abnormalities.

Williams Syndrome. Peripheral pulmonary artery stenosis is also associated with supravalvular aortic stenosis in patients with Williams syndrome, which is discussed in the section on supravalvular aortic stenosis.

Alagille Syndrome. Peripheral pulmonary artery stenosis is a component of this syndrome, with some patients having a *JAG1* mutation.

Isolated Branch Pulmonary Artery Stenosis. This is encountered mainly in the proximal left pulmonary artery and is invariably related to a sling of ductal tissue that causes stenosis when the ductus arteriosus closes after birth. In most cases it is fairly mild, but a significant obstruction resulting in failure of distal growth of the left pulmonary artery may also be seen.

Morphology. Apart from the isolated form mentioned earlier, the stenoses are usually diffuse and bilateral and extend into the mediastinal, hilar, and intraparenchymal pulmonary arteries.

Clinical Features. The degree of obstruction is the principal determinant of clinical severity. The type of obstruction determines the feasibility of intervention. Most patients are asymptomatic. An ejection systolic murmur heard at the upper left sternal border and well transmitted to the axilla and back is most common. No pulmonary ejection click is heard. The pulmonic component of the second heart sound may be accentuated and is loud only in those with proximal pulmonary hypertension. A continuous murmur is often audible in patients with significant branch stenosis. The murmurs in the lung fields are typically increased by inspiration.

Laboratory Investigations

Electrocardiography. Right ventricular hypertrophy is seen when the obstruction is severe. Left axis deviation with counterclockwise orientation of the frontal QRS vector is common in rubella syndrome and when supravalvular aortic stenosis is also present.

Chest Radiography. Mild or moderate stenosis usually produces normal findings. Detectable differences in vascularity between regions of the lungs or dilated pulmonary artery segments are uncommon. When the obstruction is bilateral and severe, right atrial and ventricular enlargement may be seen.

Echocardiography. Echocardiography is helpful in making the diagnosis and excluding associated lesions; however, it is limited in its ability to image the distal pulmonary arteries beyond the hilum of the

FIGURE e62-9 This panel shows two cases of peripheral pulmonary artery stenosis as seen on MRI. The one on the **left** shows a central proximal left pulmonary artery stenosis (*arrow*), whereas the **right** panel shows diffuse stenosis of both branch pulmonary arteries.

VIDEO 62-94

Isolated cleft of the mitral valve. This two-dimensional parasternal long-axis image shows mitral valve regurgitation originating from the cleft in the anterior leaflet.

VIDEO 62-95

Isolated cleft of the mitral valve. This two-dimensional short-axis view shows the cleft in the anterior leaflet with some thickening of the leaflet edges.

VIDEO 62-96

Isolated cleft of the mitral valve. This real-time three-dimensional image shows the isolated cleft as seen on a surgical en face view of the mitral valve. Note that it is somewhat eccentric.

VIDEO 62-97

Double-orifice mitral valve. This loop obtained in the four-chamber view shows a muscular inlet VSD, but the double-orifice mitral valve is not appreciated.

VIDEO 62-98

Double-orifice mitral valve. This short-axis view is from the same patient as in Video 62-97 and shows the double-orifice mitral valve.

VIDEO 62-99

Double-orifice mitral valve. This view is from the same patient as the two-dimensional images in Videos 62-97 and 62-98 and shows the double orifice very clearly. Some stitch artifacts can be seen in this image.

lung. Right ventricular pressure assessment may be predicted if associated tricuspid valve regurgitation is present.

Magnetic Resonance Imaging and Spiral Computed Tomography. These diagnostic tests are valuable because they permit more distal evaluation of the branch pulmonary arteries. The advantage of spiral CT in young children is that it can be performed without the need for either heavy sedation or general anesthesia. Although most patients require cardiac catheterization and angiography, these other techniques are excellent for initial evaluation and for monitoring progress of the lesions.

Radionuclide Quantitative Lung Perfusion Scan. This is valuable in patients with unilateral stenosis to determine whether intervention is necessary. Similar flow estimates can now be obtained with MRI.

Cardiac Catheterization and Angiography. This permits assessment of right ventricular pressure and pressure in the pulmonary arterial tree. Angiography is the key to precisely assessing the extent and severity of the stenoses.

Interventional Options and Outcomes. For patients with isolated left pulmonary artery stenosis and less than 30% of flow to the lung, balloon dilation with or without stent insertion is effective in relieving the obstruction. In those with more diffuse bilateral stenoses, indications for intervention depend on right ventricular pressure. Because the natural history of diffuse peripheral pulmonary artery stenosis in Williams syndrome is potential regression over time, intervention is in general reserved for patients with systemic or suprasystemic right ventricular pressure. Intervention also depends in part on the extent of the stenosis and the dilation capability of the lesions, with or without stenting. In some cases, several attempts at dilation are required to achieve any improvement in vessel caliber. High-pressure balloons are usually necessary, but some lesions cannot be dilated even with such balloons. Recently, improved results have been reported with the use of "cutting" balloons, which may assist dilation of an otherwise undilatable stenosis. As a rule, surgery has little to offer patients with diffuse peripheral pulmonary artery stenoses and can indeed make the situation worse.

Supravalvular Right Ventricular Outflow Tract Obstruction

Supravalvular right ventricular outflow tract obstruction seldom occurs in isolation. It can occur in patients with tetralogy of Fallot, Williams syndrome, Noonan syndrome, VSD, or arteriohepatic dysplasia (Alagille syndrome). Supravalvular right ventricular outflow tract obstruction can progress in severity and should be monitored. Dilation of the pulmonary trunk is not a feature of subvalvular and supravalvular right ventricular outflow tract obstruction. Intervention is recommended when the peak gradient across the right ventricular outflow tract is higher than 50 mm Hg at rest or when the patient is symptomatic.

Pulmonary Stenosis with Intact Ventricular Septum (Figs. 62-42 and e62-10)

This lesion exists as a continuum ranging from patients with isolated valvular stenosis to others with complete atresia of the pulmonary outflow tract. Two modes of manifestation exist. The first mode occurs in the neonatal period, usually with associated pathology of the tricuspid valve, right ventricle, and/or coronary arteries. The second mode is beyond the neonatal period, when the valvular stenosis is generally isolated. Some patients with severe stenosis diagnosed in utero can have valvular atresia at the time of birth.

Morphology. The pulmonary valve may vary from a well-formed trileaflet valve with varying degrees of commissural fusion to an imperforate membrane. If stenosis is present, the right ventricle is usually of normal size or only mildly hypoplastic. Patients with an imperforate valve and a patent infundibulum invariably have a larger right ventricular volume than do patients with both infundibular and valve atresia.

Clinical Features. Affected neonates often have central cyanosis because of right-to-left shunting at the atrial level and depend on a prostaglandin infusion to maintain patency of the ductus arteriosus pending balloon dilation. Auscultatory findings include a single second heart sound, no ejection click, and a murmur, which, when present, is due to tricuspid valve regurgitation. In cases beyond the newborn period, referral is usually for assessment of a cardiac murmur. It may be detected within the first few weeks of life, more commonly at the routine 6-week postnatal visit or later. These patients generally have an ejection click and a second heart sound that moves with respiration but with a soft pulmonary component. An ejection murmur of varying intensity and duration is heard best in the pulmonary area. Similarly, adults with isolated mild to moderate right ventricular outflow tract obstruction of any type usually have no symptoms. Patients with severe right ventricular outflow tract obstruction may exhibit exertional fatigue, dyspnea, lightheadedness, and chest discomfort (right ventricular angina). Physical examination may reveal a prominent jugular a wave, a right ventricular lift, and possibly a thrill in the second left intercostal space. Auscultation reveals a normal S_1 , a single or split S_2 with a diminished P_2 (unless the obstruction is supravalvular, in which case the intensity of P_2 is normal or increased), and a systolic ejection murmur best heard in the second left intercostal space. When the pulmonary valve is thin and pliable, a systolic ejection click that decreases on inspiration will be heard. As the severity of the pulmonary stenosis progresses, the interval between S_1 and the systolic ejection click becomes shorter, S_2 becomes widely split, P_2 diminishes or disappears, and the systolic ejection murmur lengthens and peaks later in systole, often extending beyond A_2 . An ejection click seldom occurs with dysplastic pulmonary stenosis. Cyanosis may be present when a PFO or ASD permits right-to-left shunting.

Adult patients with trivial and mild valvular right ventricular outflow tract obstruction do not become worse with time. Moderate valvular right ventricular outflow tract obstruction can progress in 20% of unoperated patients, especially in adults because of calcification of the valve, and may require intervention. Some of these patients can also become symptomatic, particularly in later life, because of atrial arrhythmias resulting from right ventricular pressure overload and tricuspid regurgitation. Patients with severe valvular right ventricular outflow tract obstruction will have undergone balloon or surgical valvotomy to survive to adult life. Long-term survival in patients with repaired pulmonary valve stenosis is similar to that in the general population, with excellent to good functional class at long-term follow-up in most cases. A few patients have severe pulmonary regurgitation.

Laboratory Investigations

Electrocardiography. In the newborn period the ECG may show left-axis deviation and left ventricular dominance in patients with significant right ventricular hypoplasia. Other patients may have a normal QRS axis. Right atrial overload is present in those with increased right atrial pressure. In infants, children, and adults the findings depend on the severity of the stenosis. In milder cases, findings on the ECG should be normal. As the stenosis progresses, evidence of right ventricular hypertrophy appears. Severe stenosis is seen in the form of a tall R wave in lead V_4R or V_1 with a deep S wave in V_6 . A

FIGURE 62-42 Montage of pulmonary valve stenosis demonstrating the typical pathology (left, arrow) with a thickened pulmonary valve and obstruction secondary to commissural fusion. Note the poststenotic dilation. The angiogram demonstrates a case before (middle, arrow) and during (right) balloon dilation. MPA = main pulmonary artery; RV = right ventricle.

FIGURE e62-10 Right ventriculogram (RV) in the lateral projection (**left**) from a patient with valvular pulmonic stenosis. The pulmonary valve (PV) is thickened and domes in systole (*arrows*). Poststenotic dilation of the pulmonary artery (PA) is seen. At the **right**, after successful balloon valvuloplasty, the stenotic waist (*arrow*) has almost completely disappeared. (Courtesy of Dr. Thomas G. DiSessa.)

tall QR wave in the right precordial leads with T wave inversion and ST-segment depression (right ventricular “strain”) reflects severe stenosis. When an rSR’ pattern is observed in lead V₁ (20% of patients), lower right ventricular pressure is found than in those with a pure R wave of equal amplitude. Right atrial overload is associated with moderate to severe pulmonary stenosis.

Chest Radiography. In neonates, chest radiography demonstrates pulmonary oligemia because of a right-to-left shunt at the atrial level with a prominent right heart border in those with associated tricuspid valve regurgitation. In infants, children, and adults with mild or moderate pulmonary stenosis, chest radiography often shows a heart of normal size and normal pulmonary vascularity. Poststenotic dilation of the main and left pulmonary arteries is often seen. Right atrial and right ventricular enlargement is observed in patients with severe obstruction and right ventricular failure. Pulmonary vascularity is usually normal in the absence of a right-to-left atrial shunt but may be reduced in patients with severe stenosis and right ventricular failure.

Echocardiography (Videos 62-100 and 62-101). Combined two-dimensional echocardiographic and continuous-wave Doppler examination is used to characterize the anatomic valve abnormality and its severity and has essentially eliminated the requirement for diagnostic cardiac catheterization. Although maximum instantaneous gradients have traditionally been used to select patients for balloon valvuloplasty, recent data would suggest the contrary. Mean Doppler gradients appear to correlate better with catheter-derived peak-to-peak gradients, with a value of 50 mm Hg being the cut point for intervention. Invasive studies are presently used for balloon valvuloplasty.

Right ventricular size is currently best assessed indirectly from the tricuspid annular dimension. In the absence of a VSD there is excellent correlation between the two. Right ventricular pressure can be assessed indirectly from the tricuspid regurgitation gradient. Tricuspid valve morphology and function and the status of the interatrial septum all need to be addressed.

Interventional Options and Outcomes. In neonates, prostaglandin E₁ treatment is instituted in those with ductal dependency. Following this, balloon dilation is performed in those with stenosis, whereas radiofrequency perforation in conjunction with dilation may be undertaken in those with pulmonary valve atresia (Video 62-102). If relief of the obstruction is successful, the prostaglandins are slowly weaned to determine whether the right ventricle is large enough to support the circulation. If not, a systemic-to-pulmonary artery shunt is necessary early in management. Patients in whom the ventricle is too small invariably end up on a Fontan track or 1½ ventricle repair to create a patent right ventricular outflow tract and a bidirectional cavopulmonary shunt to help unload the small ventricle. In those with a normal-sized right ventricle, no further therapy is usually necessary in the future because the stenosis recurrence rate is low. Newborns with isolated pulmonary stenosis do well after relief of the stenosis.¹²⁸

Initial encounter outside the neonatal period usually implies a well-developed right ventricle and valve, and elective balloon dilation of the pulmonary valve is the therapeutic procedure of choice, with excellent short- and medium-term results. Balloon valvuloplasty is recommended when the gradient across the right ventricular outflow tract is greater than 50 mm Hg at rest² or when the patient is symptomatic. A 2012 paper compared the outcomes after surgical and balloon pulmonary valvuloplasty.¹²⁹

Despite the excellent survival results from the second natural history study (survival rate of 95.7% after surgical valvotomy versus 96.6% in sex-matched controls), recent long-term data suggest that this patient population faces ongoing challenges. In one series, after a mean follow-up period of 33 years, 53% of the patients had required further intervention and 38% experienced either atrial or ventricular arrhythmias. In another series after balloon valvotomy, the reintervention rate at 20 years was 26%, usually for restenosis.¹²⁹ Patients who began with pulmonary atresia and an intact ventricular septum had high rates of late morbidity and mortality and arrhythmias.¹³⁰

Dysplastic Pulmonary Valve Stenosis

Morphology. In pulmonary valve stenosis caused by valvular dysplasia, the obstruction is due not to commissural fusion but to a combination of thickened and dysplastic pulmonary valve leaflets in combination with varying degrees of supravulvar pulmonary stenosis. The supravulvar stenosis is classically at the distal part of pulmonary valve sinuses, and there is usually no poststenotic pulmonary artery dilation. This entity is associated with Noonan syndrome, which in turn may be associated with hypertrophic cardiomyopathy.

Clinical Features. In most cases the diagnosis is made either during evaluation of a systolic murmur or in a child with dysmorphic features who is undergoing clinical evaluation. Children with Noonan syndrome have short stature, webbed necks, and broad-shaped chests in a fashion similar to Turner syndrome. Although this syndrome does not have an associated chromosomal abnormality, it may be familial and affects both sexes equally. A unique association in the newborn is pulmonary lymphangiectasia. The auscultatory finding that differentiates the dysplastic valves from simple pulmonary valve stenosis is the lack of an ejection click. The other features of the murmur are similar to those described in pulmonary valve stenosis.

Laboratory Investigations

Electrocardiography. The ECG is helpful in that patients with dysplastic pulmonary stenosis frequently have a leftward QRS axis, particularly when associated with hypertrophic cardiomyopathy. The remainder of the ECG is similar to that seen in patients with pulmonary valve stenosis.

Chest Radiography. The findings are similar to those of typical pulmonary valve stenosis, apart from the lack of poststenotic pulmonary trunk dilation, even in the presence of severe obstruction. In those with pulmonary lymphangiectasia, the chest radiograph has a ground-glass appearance, which can be difficult to differentiate from pulmonary venous obstruction.

Echocardiography (Video 62-103). The echocardiogram demonstrates a thickened fleshy pulmonary valve, lack of poststenotic dilation, and varying degrees of supravulvar pulmonary stenosis. The associated diagnosis of hypertrophic cardiomyopathy can be confirmed or excluded. If the initial echocardiogram does not demonstrate hypertrophic cardiomyopathy, further studies should be performed throughout childhood and adolescence, particularly in those with left-axis deviation.

Interventional Options and Outcomes

Cardiac Catheterization and Angiography. Although the results of balloon valvuloplasty are less rewarding than those in patients with stenosis secondary to commissural fusion, it is worth attempting this before considering surgical intervention. Success has been varied, with many patients having some reduction in gradient that can delay surgery.

Surgical Intervention. If balloon valvuloplasty fails, surgical intervention is indicated. It usually involves a partial valvectomy in conjunction with patch repair of the supravulvar stenosis.

Outcomes. Adequate relief of the right ventricular outflow tract obstruction results in an excellent outlook, with the greatest long-term risk factor being the presence of hypertrophic cardiomyopathy.

Subpulmonary Right Ventricular Outflow Tract Obstruction (Anomalous Muscle Bundles or a Double-Chambered Right Ventricle)

Morphology. A double-chambered right ventricle is formed by right ventricular obstruction secondary to anomalous muscle bundles. Although this pattern can occur in isolation, it is more frequently part of a combination of lesions that includes right ventricular muscle bundles, a perimembranous outlet VSD, and subaortic stenosis with or without aortic valve prolapse.

Clinical Features. Most cases are discovered as an incidental finding during routine follow-up for a VSD. Some patients may have only an ejection systolic murmur. If the obstruction is isolated, there is an ejection systolic murmur that is heard best in the upper left sternal border. If the VSD is the predominant lesion, the right ventricular outflow tract murmur may not be appreciated. Before the routine use of echocardiography, the diagnosis was often made during follow-up for a VSD when the pansystolic murmur decreased in intensity and a systolic ejection murmur emerged. Patients are usually pink unless progression of the subpulmonary stenosis occurs in the setting of a VSD. The diagnosis may be more problematic to make in adults.

Laboratory Investigations

Electrocardiography. The ECG is similar to that in those with isolated pulmonary valve stenosis beyond the newborn period. In cases with a nonrestrictive VSD and mild subpulmonary stenosis, the ECG typically shows biventricular hypertrophy from a left-to-right shunt and associated pulmonary hypertension. If the stenosis is more severe, right ventricular hypertrophy will be seen. Those with a restrictive VSD may have normal findings on the ECG or left ventricular hypertrophy, the latter of which is replaced by right ventricular hypertrophy if the subpulmonary stenosis increases in severity.

**VIDEO 62-100**

Pulmonary valve stenosis. This image of the right ventricular outflow tract shows pulmonary valve stenosis with a thickened pulmonary valve and evidence of some doming.

VIDEO 62-101

Color Doppler evaluation of a stenotic pulmonary valve.

VIDEO 62-102

This newborn has pulmonary atresia with an intact ventricular septum. The first angiogram is in the aorta to define the position of the pulmonary valve by contrast material filling the main pulmonary artery from ductal flow. The second angiogram is in the outflow tract of the hypoplastic right ventricle. The radiofrequency wire is positioned below the pulmonary valve, and perforation occurs into the main pulmonary artery. Subsequently, the valve plane is balloon-dilated, and the final angiogram confirms forward flow into the pulmonary circulation from the right ventricle.

VIDEO 62-103

Dysplastic pulmonary valve stenosis. This short-axis loop shows the typical features of a dysplastic pulmonary valve. Note the lack of poststenotic dilation, as well as a thickened fleshy valve with no evidence of doming.

Chest Radiography. Findings are usually normal in patients with isolated subpulmonary stenosis, whereas those with a VSD may have increased or reduced pulmonary blood flow, depending on the severity of the obstruction.

Echocardiography (see Videos 62-47 through 62-51). Doppler and two-dimensional echocardiography usually provide a complete diagnosis. The level of subpulmonary obstruction is appreciated best with a combination of subcostal right anterior oblique and precordial short-axis views. These views permit identification of the relationship of the VSD to the muscle bundles, as well as the degree of anterior malalignment of the infundibular septum in those with a VSD. The precordial short-axis view is the best for evaluating the presence of possible subpulmonary stenosis and aortic cusp prolapse. Color and pulsed- or continuous-wave Doppler evaluation usually allows differentiation of the VSD flow jet from that originating from the muscle bundles. This permits accurate assessment of the hemodynamic effect of the subpulmonary obstruction.

Cardiac Catheterization and Angiocardiology. This technique is rarely necessary. In older patients in whom echocardiographic images of the subpulmonary region may be suboptimal, a combination of MRA and echocardiography is all that is generally necessary.

Management Options and Outcomes. Management is dictated by the severity of the subpulmonary stenosis and the presence of associated defects. In patients with isolated subpulmonary stenosis, surgery is indicated when right ventricular pressure is more than 60% of systemic pressure. Surgery involves resection of the muscle bundles through the right atrium. In patients with an associated VSD, the decision is based on the size of the VSD, the degree of associated subaortic stenosis, the presence of aortic valve prolapse, and the severity of the subpulmonary stenosis. These patients tend to have progressive disease, so many patients who are monitored conservatively for several years will eventually require surgery. In general, the outcome is excellent with a low rate of recurrence after surgical resection of the obstructive muscle bundles. Infrequently, recurrence of the subaortic obstruction may occur.

Miscellaneous Lesions

Cor Triatriatum

Morphology. In this malformation, failure of resorption of the common pulmonary vein results in a left atrium divided by an abnormal fibromuscular diaphragm into a posterosuperior chamber receiving the pulmonary veins and an anteroinferior chamber giving rise to the left atrial appendage and leading to the mitral orifice. The communication between the divided atrial chambers may be large, small, or absent, depending on the size of the opening or openings in the diaphragm, which determines the degree of obstruction to pulmonary venous return. Elevations in both pulmonary venous pressure and pulmonary vascular resistance may result in severe pulmonary artery hypertension.

Clinical Features. Cor triatriatum may be detected as an incidental finding in a patient in whom an echocardiogram is obtained for another reason. In general, these cases represent the unobstructed form that requires no early intervention. Patients with more severe obstruction have similar findings as those with congenital pulmonary vein stenosis.

Laboratory Investigations

Electrocardiography. In unobstructed cases, findings on electrocardiography are normal, whereas patients with significant obstruction have right ventricular hypertrophy because of the associated pulmonary hypertension.

Chest Radiography. The findings may be normal in those with mild obstruction or demonstrate pulmonary edema with significant obstruction.

Echocardiography. The diagnosis is established by two-dimensional echocardiography or TEE, with further insight obtained from three-dimensional reconstruction. The obstructive diaphragm is visualized on parasternal long- and short-axis and four-chamber views and can be distinguished from a supravulvar mitral ring by its position superior to the left atrial appendage, which forms part of the distal chamber. Also present is diastolic fluttering of the mitral leaflets and high-velocity flow detected by Doppler examination in the distal atrial chamber and at the mitral orifice (Videos 62-104 through 62-106).

Cardiac Catheterization and Angiocardiology. This technique is usually unnecessary since the advent of echocardiography and MRI.

Management Options and Outcomes. Surgical resection of the membrane is the treatment of choice for patients with significant

obstruction. It results in relief of symptoms and a reduction in pulmonary artery pressure. In general, the outcome following surgery is good. With the advent of more routine echocardiography, a subset of patients with typical but nonobstructive forms has been recognized. Thus far these patients appear to remain asymptomatic, with infrequent need for surgical intervention.

Pulmonary Vein Stenosis

Congenital pulmonary vein stenosis may occur as a focal stenosis at the atrial junction or as generalized hypoplasia of one or more pulmonary veins. The incidence of associated cardiac malformations is extremely high, including VSD, ASD, tetralogy of Fallot, tricuspid and mitral atresia, and AV septal defect. In other cases the pulmonary vein stenosis is acquired after surgical intervention for total anomalous pulmonary venous connection. Children frequently have recurrent respiratory infections, whereas adults exhibit exercise intolerance. Pulmonary hypertension is one of the consequences of pulmonary vein stenosis, regardless of whether it is congenital or acquired. In patients with unilateral pulmonary vein stenosis, clinical symptoms are frequently absent because of redistribution of pulmonary blood flow away from the affected lung.

Laboratory Investigations

Electrocardiography. Findings on the ECG are usually normal unless there is evidence of pulmonary hypertension, in which case right ventricular hypertrophy may be seen.

Chest Radiography. With unilateral pulmonary vein stenosis there is oligemia of the affected lung and increased flow to the contralateral side. If the obstruction is bilateral, pulmonary edema is seen.

Echocardiography. This can usually exclude or confirm the diagnosis of pulmonary vein stenosis. Assessment of pulmonary artery pressure from tricuspid or pulmonary valve regurgitation is possible. Doppler color flow assessment of the right- and left-sided pulmonary veins is the best screening tool. In patients with evidence of turbulence or aliasing in the color flow pattern, spectral analysis with pulsed Doppler will help confirm the diagnosis. Usually, pulmonary venous flow is low velocity and phasic. If the pattern is high velocity and turbulent, disturbed pulmonary venous flow is present. Absolute Doppler gradients may or may not be helpful for two reasons. First, absolute velocity depends on the amount of pulmonary blood flow to that segment of lung. Second, it is often difficult to obtain a parallel line of interrogation of the pulmonary veins, which will affect assessment of the gradient. Absolute velocity is less important than the diagnosis of pulmonary vein stenosis and its effect on pulmonary artery pressure.

Magnetic Resonance Imaging (Fig. e62-11). This technique has now become the gold standard for diagnosis of pulmonary vein stenosis. MRI permits detailed assessment of the pulmonary veins. Assessment of velocity is now possible, although this is in the actual veins themselves rather than at the venoatrial junction, which is the site assessed by Doppler echocardiography.

Cardiac Catheterization and Angiocardiology. In general, a combination of echocardiography and MRI makes invasive procedures unnecessary.

Management Options and Outcomes. If the patient has unilateral pulmonary vein stenosis and normal pulmonary artery pressure, no treatment may be necessary. Continued follow-up is important because this is often a progressive disease that can subsequently affect both sides. In patients with bilateral stenoses the outlook in the past was believed to be hopeless, with virtually 100% mortality. Stents usually provided only temporary relief. More recently, a pericardial reflection procedure using native tissue has resulted in some early success in treating this lesion. It involves using native atrial tissue to form a pocket around the surgically resected stenotic region.

Partial Anomalous Pulmonary Venous Connection

Morphology. PAPVC refers to conditions in which part or all of one lung drains to a site other than the left atrium. Sinus venosus defects are associated with PAPVC typically from the right upper and middle lobe pulmonary veins to the superior vena cava. PAPVC may be directed to a left vertical vein, to the superior vena cava at the level of or above the right pulmonary artery, to the azygos vein, or to the coronary sinus (Video 62-107). PAPVC to the inferior vena cava (scimitar syndrome) may have associated hypoplasia of the right lung, pulmonary sequestration, and abnormal collateral supply to the sequestered segment. It can be seen in some patients (~10%) with a secundum ASD, as well as in association with many other forms of CHD. With PAPVC to the right atrium the pulmonary veins lie in the

FIGURE e62-11 Three-dimensional MRI demonstrating stenosis of the left lower lobe pulmonary vein. AO = aorta; LPV = left pulmonary vein; PA = pulmonary artery.

VIDEO 62-104

Cor triatriatum. This long-axis loop shows the dividing membrane in the left atrium. Note that it sits above the AV groove.

VIDEO 62-105

Four-chamber loop showing cor triatriatum. Note the extent of the left atrial membrane, which lies above the left atrial appendage.

VIDEO 62-106

Cor triatriatum. This color loop shows that although the left atrial membrane appears to cross from medial to lateral, there is an adequate orifice because of the lack of evidence of stenosis.

VIDEO 62-107

An elderly man was evaluated for dyspnea and an ASD was found. Further investigation suggested anomalous drainage of the left lung. Angiography in the left pulmonary artery reveals that the left lung drains through a vertical vein into the innominate vein and then into the superior vena cava. A second angiogram in the vertical vein itself is then presented.

normal position; however, the septum primum is deviated to the left with absence of the septum secundum. This type of lesion is seen more frequently in hearts with visceral heterotaxy.

Clinical Features. In the absence of associated anomalies, the physiologic disturbance is determined by the number of anomalous veins and their site of connection, the presence and size of an ASD, and the state of the pulmonary vascular bed. In the usual patient with an isolated partial pulmonary venous connection, the hemodynamic state and physical findings are similar to those in patients with an ASD.

Laboratory Investigations

Electrocardiography. In isolated cases, findings similar to a secundum ASD may be seen.

Chest Radiography. Isolated cases show cardiomegaly involving the right ventricle with increased pulmonary vascular markings. Patients with scimitar syndrome typically exhibit right lung hypoplasia with a secondary shift of the heart into the right thorax and a right-sided scimitar sign that represents the anomalous pulmonary vein.

Echocardiography. In patients with a significant left-to-right shunt, right ventricular volume overload with paradoxical interventricular septal motion is present. A dilated coronary sinus is seen in PAPVC to the coronary sinus. In scimitar syndrome the abnormal pulmonary vein can be seen from the subcostal position during evaluation of the inferior vena cava. Associated stenosis of the pulmonary vein may exist. The suprasternal position permits identification of a left vertical vein, and in general it is possible in children to identify the number of connecting veins on that side. Abnormal venous drainage to the right superior vena cava may be more difficult to identify unless a systematic approach is undertaken. The suprasternal frontal plane view allows identification of veins that connect just above the right pulmonary artery. Those that connect just behind the right pulmonary artery, either into the superior vena cava or into the azygos, can be identified with a right anterior oblique view of the superior vena cava, whether from the subcostal position or from a high right parasternal location. In adults, TEE may also be useful in detecting PAPVC.

Magnetic Resonance Imaging. Although TEE can be used with a considerable degree of accuracy in older patients who have a poorer ultrasound window, it is less invasive to obtain the data with MRI. It provides superb images of the connecting veins, which can be seen more distally to their connections with the hilum of the lung. The pulmonary-to-systemic flow ratio can be calculated, thereby obviating the need for hemodynamic evaluation. The pulmonary-to-systemic flow ratio can also be calculated by radionuclide techniques.

Management Options. In patients with a volume-loaded right ventricle, surgical intervention should be considered. Surgery is not necessary when a single anomalously draining vein has not produced right ventricular volume loading. Surgery is typically performed at approximately 3 to 5 years of age, similar to an ASD. The type of surgery depends on the location of the drainage but in general consists of reconnecting the abnormal vein or veins to the left atrium, either directly in the case of a left vertical vein or via a baffle in most other instances. In scimitar syndrome, occlusion of the collateral arteries may be necessary, as well as redirection of the pulmonary veins.

Outcomes. In general, patients with repaired PAPVC have a good outcome, similar to that in patients with an isolated ASD. What is unclear is the exact patency rate of the veins that are reconnected or baffled back to the left atrium. Patients with scimitar syndrome fare well if the lesion is relatively isolated but do poorly if significant associated intracardiac pathology is present.

Pulmonary Arteriovenous Fistula

Abnormal development of the pulmonary arteries and veins in a common vascular complex is responsible for this congenital anomaly. A variable number of pulmonary arteries communicate directly with branches of the pulmonary veins. Most patients have an associated Weber-Osler-Rendu syndrome; accompanying problems include bronchiectasis and other malformations of the bronchial tree, as well as absence of the right lower lobe. Pulmonary AV fistulas may also complicate the classic Glenn shunts used for the palliation of cyanotic CHD and are believed to be due to the absence of "hepatic factor" in the venous blood feeding the superior vena cava–pulmonary artery connection. Hepatopulmonary syndrome may also be associated with substantial right-to-left intrapulmonary shunting.⁶⁷ The amount of right-to-left shunting depends on the extent of the fistulous communications and may result in cyanosis. Paradoxical emboli or a brain abscess may result and cause major neurologic deficits. Patients with hereditary hemorrhagic telangiectasia are often anemic because of repeated blood loss and may have less obvious cyanosis because of

anemia. Systolic and continuous murmurs may be audible over areas of the fistula. Rounded opacities of various sizes in one or both lungs on chest radiography may suggest the presence of the lesion.

Laboratory Investigations. Echocardiography with injection of saline contrast medium into a systemic vein is helpful in the initial diagnostic process. Patients with pulmonary arteriovenous malformations have early pulmonary venous return to the left atrium, but not as quickly as in those with a PFO or ASD and right-to-left atrial shunting. More recently, CT and MRI techniques have provided valuable diagnostic information. Pulmonary angiography reveals the site and extent of the abnormal communication.

Management Options. Unless the lesions are widespread throughout both lungs, surgical treatment aimed at removing the lesions with preservation of healthy lung tissue is commonly indicated to avoid the complications of massive hemorrhage, bacterial endocarditis, and rupture of arteriovenous aneurysms. Transcatheter balloon or plug or coil occlusion embolotherapy may prove to be the therapeutic procedure of choice in some patients.

Coronary Arteriovenous Fistula

Morphology. A coronary arteriovenous fistula is a communication between one of the coronary arteries and a cardiac chamber or vein. The right coronary artery (or its branches) is the site of the fistula in approximately 55% of patients, the left coronary artery is involved in approximately 35%, and both coronary arteries are involved in a few. Connections between the coronary system and a cardiac chamber appear to represent persistence of the embryonic intertrabecular spaces and sinusoids. Most of these fistulas drain into the right ventricle, right atrium, or coronary sinus. Coronary-to-pulmonary artery fistulas are an occasional and usually incidental finding in the adult coronary angiography suite.

Clinical Features. The shunt through the fistula is generally small, and myocardial blood flow is not compromised. Potential complications include pulmonary hypertension and congestive heart failure if a large left-to-right shunt exists, bacterial endocarditis, rupture or thrombosis of the fistula or an associated arterial aneurysm, and myocardial ischemia distal to the fistula as a result of "myocardial steal."

Most pediatric patients are asymptomatic and are referred because of a cardiac murmur that is loud, superficial, and continuous at the lower or midsternal border. The site of maximal intensity of the murmur is related to the site of drainage and is generally away from the second left intercostal space—the classic site of the continuous murmur of persistent ductus arteriosus.

Laboratory Investigations

Electrocardiography. Findings on the ECG are usually normal unless a large left-to-right shunt is present.

Chest Radiography. Radiographic findings are often normal and seldom show selective chamber enlargement.

Echocardiography. Coronary artery fistulas are now recognized with a high degree of accuracy with the advent of routine coronary artery evaluation during most pediatric echocardiography examinations. A significantly enlarged feeding coronary artery can be detected, and the entire course and site of entry of the arteriovenous fistula can be traced by Doppler color flow mapping. The shunt entry site is characterized by a continuous turbulent systolic and diastolic flow pattern. Multiplane TEE also accurately defines the origin, course, and drainage site of the fistula.

Cardiac Catheterization and Angiocardiology. If echocardiography demonstrates a significant coronary artery fistula, hemodynamic evaluation is warranted. Standard retrograde thoracic aortography, balloon occlusion angiography of the aortic root with a 45-degree caudal tilt of the frontal camera ("laid back" aortogram), or coronary arteriography can be used to reliably identify the size and anatomic features of the fistulous tract.

Management Options and Outcomes. Small fistulas have an excellent long-term prognosis. Untreated larger fistulas may predispose the individual to premature coronary artery disease in the affected vessel. Coil embolization at the time of cardiac catheterization is rapidly becoming the treatment of choice (Video 62-108). Surgical treatment is still required in some instances.

**VIDEO 62-108**

This 5-year-old had a circumflex-to-left ventricular fistula. Via a femoral artery-to-femoral artery loop, a vascular plug was introduced from the left ventricular side into the fistula. The last injection with the device released reveals correct positioning and a persistent shunt, which resolved completely within 24 hours as confirmed by echocardiography.

OVERVIEW

Valvular heart disease accounts for 10% to 20% of all cardiac surgical procedures in the United States. The primary causes of valve disease are age-associated calcific valve changes and inherited or congenital conditions (e.g., a bicuspid aortic valve or myxomatous mitral valve disease). The prevalence of rheumatic valve disease now is very low in the United States and Europe because of primary prevention of rheumatic fever, although rheumatic valve disease remains prevalent in the developing world (see Chapter 83). Approximately two thirds of all heart valve operations are for aortic valve replacement (AVR), most often for aortic stenosis (AS). Mitral valve surgery most often is performed for mitral regurgitation (MR); most patients with mitral stenosis (MS) are treated by a percutaneous approach.^{1,2} In addition to patients with severe valve disease that eventually will require mechanical intervention, there is a larger group of patients with mild to moderate disease who need accurate diagnosis and appropriate medical management. Newer transcatheter techniques for treatment of valve dysfunction, including transcatheter aortic valve implantation (TAVI), device closure of paravalvular regurgitation, and several other methods (some investigational) of catheter-based mitral valve repair, are transforming our approach to the management of patients with valvular heart disease (see Chapter 56). In addition, increased understanding of the basic biologic mechanisms leading to valve dysfunction offers the hope of effective medical interventions to prevent or slow the disease process in the near future. Treatment paradigms are shifting toward a multidisciplinary approach to patient management, involving cardiologists (invasive and noninvasive), surgeons, and nurses with expertise in valvular heart disease. This trend has stimulated the development of multispecialty care teams working together within institutional heart valve centers (Fig. 63-1; see also

Table e63-1).

AORTIC VALVE DISEASE

Aortic Stenosis

Causes and Pathology

Valvular AS has three principal causes: a congenital bicuspid valve with superimposed calcification, calcification of a normal trileaflet valve, and rheumatic disease (Fig. 63-2). In a U.S. series of 933 patients undergoing AVR for AS, a bicuspid valve was present in more than 50%, including two thirds of those younger than 70 years and 40% of those older than 70 years of age.³

In addition, AS may be caused by a congenital valve stenosis manifesting in infancy or childhood. Rarely, AS is caused by severe atherosclerosis of the aorta and aortic valve; this form of AS occurs most frequently in patients with severe hypercholesterolemia and is

observed in children with homozygous type II hyperlipoproteinemia. Rheumatoid involvement of the valve is a rare cause of AS and results in nodular thickening of the valve leaflets and involvement of the proximal portion of the aorta. Ochronosis with alkaptonuria is another rare cause of AS.

Fixed obstruction to left ventricular (LV) outflow also may occur above the valve (supravalvular stenosis) or below the valve (discrete subvalvular stenosis; see Fig. 14-46) (Videos 63-1A and 63-1B); dynamic subaortic obstruction may be caused by hypertrophic cardiomyopathy (HCM) (see Chapter 66).

Congenital Aortic Valve Disease. Congenital malformations of the aortic valve (see Chapter 62) may be unicuspid, bicuspid, or tricuspid, or the anomaly may manifest as a dome-shaped diaphragm (see Fig. 14-45). Unicuspid valves typically produce severe obstruction in infancy and are the most frequent malformations found in fatal valvular AS in children younger than 1 year but also may be seen in young adults with an anatomy that mimics bicuspid valve disease. Congenitally bicuspid valves rarely are responsible for serious narrowing of the aortic orifice during childhood⁴ but do cause significant aortic regurgitation (AR) requiring valve surgery in young adulthood in a subset of patients. Most affected patients, however, have normal valve function until late in life, when superimposed calcific changes result in valve obstruction (see later under **Bicuspid Aortic Valve Disease**).

Calcific Aortic Valve Disease. Calcific aortic valve disease (formerly termed *senile* or *degenerative*) affecting a congenital bicuspid or normal trileaflet valve is now the most common cause of AS in adults. In a population-based echocardiographic study, 2% of persons 65 years of age or older had significant calcific AS (see Chapter 76), whereas 29% exhibited age-related aortic valve sclerosis without stenosis, defined as irregular thickening of the aortic valve leaflets detected by echocardiography without significant obstruction.⁵ Aortic sclerosis, identified by either echocardiography or computed tomography (CT), is the initial stage of calcific valve disease and, even in the absence of valve obstruction or known cardiovascular disease, is associated with a 50% increased risk of cardiovascular death and myocardial infarction over approximately 5 years of follow-up.^{6,7} Significant associations have been documented between calcific aortic valve disease and cardiovascular risk factors (Table 63-1).

Although calcific AS once was considered to represent the result of years of normal mechanical stress on an otherwise normal valve, the evolving concept is that the disease process represents proliferative and inflammatory changes, with lipid accumulation, upregulation of angiotensin-converting enzyme (ACE) activity, increased oxidative stress, and infiltration of macrophages and T lymphocytes⁸⁻¹² (Fig. 63-3) ultimately leading to bone formation¹³⁻¹⁵ in a manner similar, but not identical, to that for vascular calcification. Progressive calcification, initially occurring along the flexion lines at their bases, leads to immobilization of the cusps. A high prevalence of calcific AS also exists in patients with Paget disease of bone and end-stage renal disease.

Age-related calcific AS shares common risk factors with mitral annular calcification, and the two conditions often coexist. Genetic

TABLE e63-1 Specific Aims of the Heart Valve Clinic

- To improve the outcome of patients with valvular heart disease
- To ensure optimal communication and coordination among all health care professionals involved in the management of patients with valvular heart disease
- To perform or coordinate relevant diagnostic tests to obtain a complete evaluation of the severity of valvular heart disease and its implications for symptomatic status, cardiac function, and risk of future adverse events
- To ensure rational utilization of diagnostic tests according to the recommendations of international guidelines
- To standardize and centralize the collection and interpretation of the results of these tests and provide all health care professionals involved in management of the patient with complete and accurate information concerning the diagnosis and prognosis of valvular heart disease
- To optimize patient education concerning compliance with medical therapy and prompt reporting of symptoms relating to valvular heart disease
- To assist the general cardiologist with regard to prescription of appropriate pharmacologic treatment and determination of the most appropriate timing for clinical evaluation, imaging, exercise testing, and follow-up before and after valve procedures
- To assist the general cardiologist in the determination of the optimal timing and mode of intervention
- To enhance adherence to international guidelines for the evaluation and management of patients with valvular heart disease

polymorphisms have been linked to the presence of calcific AS, including those involving the vitamin D receptor, interleukin-10 alleles, and the apolipoprotein E4 allele (Table 63-2). Familial clustering of calcific AS also has been described, suggesting a possible genetic predisposition to valve calcification.^{16,17} The risk factors for the development of calcific AS are similar to those for vascular atherosclerosis—elevated serum levels of low-density lipoprotein (LDL) cholesterol and lipoprotein(a) [Lp(a)], diabetes, smoking, and hypertension.^{5,6,18} Calcific AS also has been linked to inflammatory markers and components of the metabolic syndrome. In a genome-wide association study based on a meta-analysis of data on nearly 7000 patients from three population-based

cohorts, a single-nucleotide polymorphism in the locus for LDL was associated with aortic valve calcification, serum Lp(a) levels, and incident aortic stenosis (hazard ratio [HR], 1.68; CI, 1.32 to 2.15).¹⁹ This correlation was confirmed by review of a large Danish registry of more than 77,000 patients in whom two Lp(a) genotypes were significantly associated with incident AS.²⁰ The growing consensus, therefore, is that “degenerative” calcific AS shares many pathophysiologic features with atherosclerosis and that specific pathways might be targeted to prevent or retard disease progression.^{5,11,13,21}

Rheumatic Aortic Stenosis. Rheumatic AS results from adhesions and fusions of the commissures and cusps and vascularization of the

FIGURE 63-3 Disease progression in calcific aortic stenosis, showing changes in aortic valve histologic features, leaflet opening in systole, and Doppler velocities. **A**, The histology of the early lesion is characterized by a subendothelial accumulation of oxidized LDL, production of angiotensin (Ang II), and inflammation with T lymphocytes and macrophages. Disease progression occurs by several mechanisms, including local production of proteins, such as osteopontin, osteocalcin, and bone morphogenetic protein 2 (BMP-2), which mediate tissue calcification; activation of inflammatory signaling pathways, including tumor necrosis factor (TNF), tumor growth factor-beta (TGF- β), the complement system, C-reactive protein, and interleukin-1 β ; and changes in tissue matrix, including the accumulation of tenascin C and upregulation of matrix metalloproteinase 2 and alkaline phosphatase activity. In addition, leaflet fibroblasts undergo phenotypic transformation into osteoblasts, regulated by the Wnt3-Lrp5- β catenin signaling pathway. Microscopic accumulations of extracellular calcification (Ca^{2+}) are present early in the disease process, with progressive calcification as the disease progresses and areas of frank bone formation in end-stage disease. **B**, The corresponding changes in aortic valve anatomy are viewed from the aortic side with the valve open in systole. **C**, Corresponding changes in Doppler aortic jet velocity. (From Otto CM: *Calcific aortic stenosis—time to look more closely at the valve*. *N Engl J Med* 359:1395, 2008.)

From Owens DS, O'Brien KD: Clinical and genetic risk factors for calcific valve disease. In Otto CM, Bonow RO (eds): Valvular Heart Disease: A Companion to Braunwald's Heart Disease. 4th ed. Philadelphia, Saunders, 2013, pp 53-62.

leaflets of the valve ring, leading to retraction and stiffening of the free borders of the cusps. Calcific nodules develop on both surfaces, and the orifice is reduced to a small round or triangular opening (see Fig. 63-2C). As a consequence, the rheumatic valve often is regurgitant as well as stenotic. Patients with rheumatic AS invariably have rheumatic involvement of the mitral valve (see Chapter 83). With the decline in rheumatic fever in developed nations, rheumatic AS is decreasing in frequency, although it continues to be a major problem on a worldwide basis.

Pathophysiology

In adults with calcific AS, a significant burden of leaflet disease is present before obstruction to outflow develops. However, once even mild obstruction is present, hemodynamic progression occurs in almost all patients, with the interval from mild to severe obstruction ranging from less than 5 to more than 10 years (Fig. 63-4). In infants and children with congenital AS, the valve orifice shows little change as the child grows, thereby contributing to the relative obstruction over time. The clinical stages reflecting the progression of aortic stenosis are shown in Table 63-3.

Severe obstruction to LV outflow usually is characterized by the following: (1) an aortic jet velocity of 4 m/sec or greater; (2) a mean systolic pressure gradient at least 40 mm Hg in the presence of a normal cardiac output; or (3) an effective aortic orifice (calculated by the continuity equation; see Fig. 14-49) no greater than 1.0 cm² in an average-sized adult (i.e., <0.6 cm²/m² of body surface area, approximately 25% of the normal aortic orifice of 3.0 to 4.0 cm²). An aortic valve orifice area between 1.0 to 1.5 cm² is considered to represent moderate stenosis, and an orifice measuring greater than 1.5 to 2.0 cm² is referred to as mild stenosis^{1,5,22,23} (see Table 63-3). The degree of stenosis associated with symptom onset varies among patients, however, and no single number defines severe or critical AS in an individual patient. Clinical decisions are based on

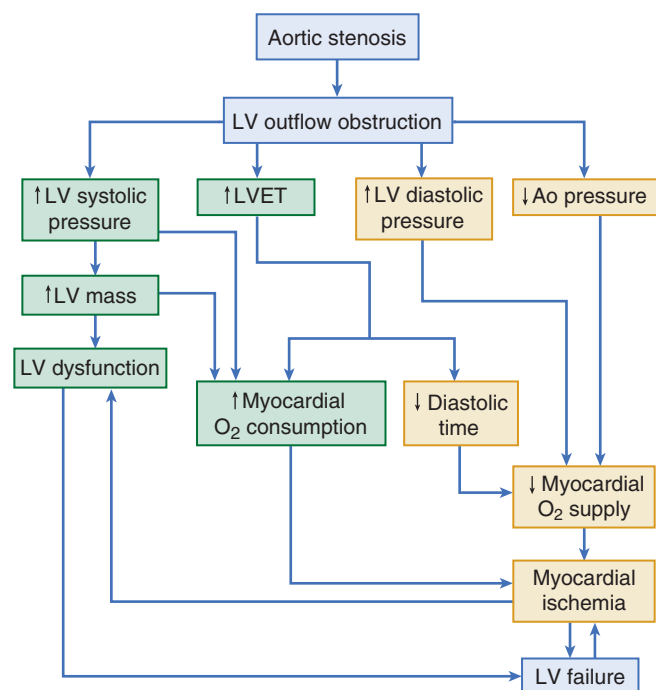

FIGURE 63-4 Pathophysiology of aortic stenosis. LV outflow obstruction results in an increased LV systolic pressure, increased LV ejection time (LVET), increased LV diastolic pressure, and decreased aortic (Ao) pressure. Increased LV systolic pressure with LV volume overload increases LV mass, which may lead to LV dysfunction and failure. Increased LV systolic pressure, LV mass, and LVET increase myocardial oxygen (O_2) consumption. Increased LVET results in a decrease of diastolic time (myocardial perfusion time). Increased LV diastolic pressure and decreased Ao diastolic pressure decrease coronary perfusion pressure. Decreased diastolic time and coronary perfusion pressure decrease myocardial O_2 supply. Increased myocardial O_2 consumption and decreased myocardial O_2 supply produce myocardial ischemia, which further deteriorates LV function. (From Boudoulas H, Gravanis MB: *Valvular heart disease*. In Gravanis MB [ed]: *Cardiovascular Disorders: Pathogenesis and Pathophysiology*. St. Louis, CV Mosby, 1993, p 64.)

consideration of symptom status and the LV response to chronic pressure overload, in conjunction with hemodynamic severity. In some cases, additional measures of hemodynamic severity, such as the energy loss index, valvular impedance, or evaluation with changing loading conditions (e.g., dobutamine stress) or with exercise, are necessary for full evaluation of disease severity.²⁴⁻²⁸

Chronic pressure overload typically results in concentric LV hypertrophy, with increased wall thickness and a normal chamber size. The increased wall thickness allows normalization of wall stress (afterload) so that LV contractile function is maintained. However, the increased myocardial cell mass and increased interstitial fibrosis result in diastolic dysfunction, which may persist even after relief of AS. Sex differences in the LV response to AS have been reported, with women more frequently exhibiting normal LV performance and a smaller, thicker-walled, concentrically hypertrophied left ventricle with diastolic dysfunction and normal or even subnormal systolic wall stress. Men more frequently demonstrate eccentric LV hypertrophy, excessive systolic wall stress, systolic dysfunction, and chamber dilation.

The LV changes caused by chronic pressure overload are reflected in the LV and left atrial pressure waveforms and Doppler velocity curves. As contraction of the left ventricle becomes progressively more isometric, the LV pressure pulse exhibits a rounded, rather than flattened, summit, and the Doppler velocity curve exhibits a progressively later systolic peak. The elevated LV end-diastolic pressure and the corresponding Doppler changes in LV filling, which are characteristic of severe AS, reflect delayed relaxation and eventually decreased compliance of the hypertrophied LV wall. In patients with severe AS, large *a* waves usually appear in the left atrial pressure pulse and Doppler LV filling curve because of the combination of

enhanced contraction of a hypertrophied left atrium and diminished LV compliance. Atrial contraction plays a particularly important role in filling of the left ventricle in AS: It raises LV end-diastolic pressure without causing a concomitant elevation of mean left atrial pressure. This “booster pump” function of the left atrium prevents the pulmonary venous and capillary pressures from rising to levels that would produce pulmonary congestion, while at the same time maintaining LV end-diastolic pressure at the elevated level necessary for effective contraction of the hypertrophied left ventricle. These changes in diastolic function are reflected in the Doppler parameter of LV filling and noninvasive measures of diastolic function, such as strain and strain rate (see Chapter 14). Loss of appropriately timed, vigorous atrial contraction, as occurs in atrial fibrillation (AF) or atrioventricular dissociation, may result in rapid clinical deterioration in patients with severe AS.

Systemic vascular resistance also contributes to total LV afterload in adults with AS. Concurrent hypertension increases total LV load and may affect the evaluation of AS severity.²⁹ Pulmonary hypertension is present in approximately 50% of adults undergoing AVR for severe AS and is associated with decreased long-term survival.^{30,31} The elevated pulmonary vascular resistance in AS patients decreases, with phosphodiesterase type 5 inhibition suggesting that the mechanism of pulmonary hypertension is increased LV preload and afterload.³²

Exercise physiology is abnormal in adults with moderate to severe AS, and even asymptomatic patients have a reduced exercise tolerance. Although cardiac output at rest is within normal limits, the normal increase in cardiac output with exercise is blunted and is mediated primarily by increased heart rate, with little change in stroke volume. Even though stroke volume is unchanged, transvalvular flow rate increases because of the shortened systolic ejection period so that aortic jet velocity and transvalvular gradient increase proportionally. Before symptom onset, valve area increases slightly with exercise (by 0.2 cm² on average), but as AS becomes more severe and symptoms are imminent, valve area becomes fixed, resulting in an even greater rise in jet velocity and pressure gradient with exercise. At this point, there is an abnormal blood pressure response to exercise (rise in systolic blood pressure <10 mm Hg), signifying severe valve obstruction.

Myocardial Function in Aortic Stenosis

When the aorta is suddenly constricted in experimental animals, LV pressure rises, wall stress increases significantly, and both the extent and velocity of shortening decline. The development of LV hypertrophy is one of the principal mechanisms whereby the heart adapts to such an increased hemodynamic burden (see Chapter 21). The increased systolic wall stress induced by AS leads to parallel replication of sarcomeres and concentric hypertrophy. The increase in LV wall thickness is often sufficient to counterbalance the increased pressure so that peak systolic wall tension returns to normal, or remains normal, if the obstruction develops slowly. An inverse correlation between wall stress and ejection fraction has been described in patients with AS. This suggests that the depressed ejection fraction and velocity of fiber shortening that occur in some patients are a consequence of inadequate wall thickening, resulting in afterload mismatch. In others, the lower ejection fraction is secondary to a true depression of contractility; in this group, surgical treatment is less effective. Thus both increased afterload and altered contractility are operative to a variable extent in depressing LV performance. To evaluate myocardial function in patients with AS, ejection phase indices, such as ejection fraction and myocardial fiber shortening, should be related to the existing wall tension.³³

Diastolic Properties

Although LV hypertrophy is a key adaptive mechanism to the pressure load imposed by AS, it has an adverse pathophysiologic consequence (i.e., it increases diastolic stiffness; see Chapters 21 and 27). As a result, greater intracavitary pressure is required for LV filling. Some patients with AS exhibit an increase in stiffness of the left

TABLE 63-3 Stages of Valvular Aortic Stenosis

A	At risk of AS	Bicuspid aortic valve (or other congenital valve anomaly) Aortic valve sclerosis	Aortic Vmax <2 m/sec	None	None
B	Progressive AS	Mild to moderate leaflet calcification of a bicuspid or trileaflet valve with some reduction in systolic motion or Rheumatic valve changes with commissural fusion	Mild AS: Aortic Vmax 2.0-2.9 m/sec or mean ΔP <20 mm Hg Moderate AS: Aortic Vmax 3.0-3.9 m/sec or mean ΔP 20-39 mm Hg	Early LV diastolic dysfunction may be present Normal LVEF	None
C	Asymptomatic severe AS				
C1	Asymptomatic severe AS	Severe leaflet calcification or congenital stenosis with severely reduced leaflet opening	Severe AS: Aortic Vmax ≥ 4 m/sec or mean $\Delta P \geq 40$ mm Hg AVA typically is ≤ 1 cm ² (or AVAi ≤ 0.6 cm ² /m ²) Very severe AS is an aortic Vmax ≥ 5 m/sec, or mean $\Delta P \geq 60$ mm Hg	LV diastolic dysfunction Mild LV hypertrophy Normal LVEF	None—exercise testing is reasonable to confirm symptom status
C2	Asymptomatic severe AS with LV dysfunction	Severe leaflet calcification or congenital stenosis with severely reduced leaflet opening	Aortic Vmax ≥ 4 m/sec or mean $\Delta P \geq 40$ mm Hg AVA typically is ≤ 1 cm ² (or AVAi ≤ 0.6 cm ² /m ²)	LVEF <50%	None
D	Symptomatic severe AS				
D1	Symptomatic severe high-gradient AS	Severe leaflet calcification or congenital stenosis with severely reduced leaflet opening	Severe AS: Aortic Vmax ≥ 4 m/sec, or mean $\Delta P \geq 40$ mm Hg AVA typically is ≤ 1 cm ² (or AVAi ≤ 0.6 cm ² /m ²), but may be larger with mixed AS/AR	LV diastolic dysfunction LV hypertrophy Pulmonary hypertension may be present	Exertional dyspnea or decreased exercise tolerance Exertional angina Exertional syncope or presyncope
D2	Symptomatic severe low-flow/low-gradient AS with reduced LVEF	Severe leaflet calcification with severely reduced leaflet motion	AVA ≤ 1 cm ² with resting aortic Vmax <4 m/sec, or mean ΔP <40 mm Hg Dobutamine stress echo shows AVA ≤ 1 cm ² with Vmax ≥ 4 m/sec at any flow rate	LV diastolic dysfunction LV hypertrophy LVEF <50%	HF, Angina, Syncope or presyncope
D3	Symptomatic severe low-gradient AS with normal LVEF or paradoxical low-flow severe AS	Severe leaflet calcification with severely reduced leaflet motion	AVA ≤ 1 cm ² with aortic Vmax <4 m/sec, or mean ΔP <40 mm Hg AVAi ≤ 0.6 cm ² /m ² Stroke volume index <35 mL/m ² Measured when the patient is normotensive (systolic BP <140 mm Hg)	Increased LV relative wall thickness Small LV chamber with low-stroke volume. Restrictive diastolic filling LVEF $\geq 50\%$	HF, Angina, Syncope or presyncope

AVA = aortic valve area; AVAi = aortic valve area indexed to body surface area; BP = blood pressure; HF = heart failure; LVEF = left ventricular ejection fraction; ΔP = pressure gradient; Vmax = maximum aortic velocity.

From Nishimura RA, Otto CM, Bonow RO, et al: 2014 AHA/ACC guideline for the management of patients with valvular heart disease: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 63:e57, 2014.

ventricle (increased chamber stiffness) simply because of increased muscle mass with no alteration in the diastolic properties of each unit of myocardium (normal muscle stiffness); others show increases in chamber and muscle stiffness. This increased stiffness, however produced, contributes to the elevation of LV diastolic filling pressure at any level of ventricular diastolic volume. Diastolic dysfunction may revert toward normal with regression of hypertrophy after surgical relief of AS, but some degree of long-term diastolic dysfunction typically persists.

Ischemia

In patients with AS, coronary blood flow at rest is elevated in absolute terms but is normal when corrections are made for myocardial mass. Reduced coronary blood flow reserve may produce inadequate myocardial oxygenation in patients with severe AS, even in the absence

of coronary artery disease. The hypertrophied LV muscle mass, increased systolic pressure, and prolongation of ejection all elevate myocardial oxygen consumption. The abnormally heightened pressure compressing the coronary arteries may exceed the coronary perfusion pressure and the shortening of diastole interferes with coronary blood flow, thus leading to an imbalance between myocardial oxygen supply and demand (see Fig. 63-4).³⁴ Myocardial perfusion also is impaired by the relative decrease in myocardial capillary density as myocardial mass increases and by the elevation of LV end-diastolic pressure, which lowers the aortic-LV pressure gradient in diastole (i.e., the coronary perfusion pressure gradient). This underperfusion may be responsible for the development of subendocardial ischemia, especially when oxygen demand is increased or the diastolic filling period is reduced (e.g., with tachycardia, anemia, infection, or pregnancy).

Clinical Presentation

Symptoms. The cardinal manifestations of acquired AS are exertional dyspnea, angina, syncope, and ultimately heart failure^{5,35,36}. Most patients now are diagnosed before symptom onset on the basis of the finding of a systolic murmur on physical examination, with confirmation of the diagnosis by echocardiography. Symptoms typically begin at age 50 to 70 years with bicuspid aortic valve stenosis and in those older than 70 years with calcific stenosis of a trileaflet valve, although even in this age group approximately 40% of patients with AS have a congenital bicuspid valve.³

The most common clinical presentation in patients with a known diagnosis of AS who are followed prospectively is a gradual decrease in exercise tolerance, fatigue, or dyspnea on exertion. The mechanism of exertional dyspnea may be LV diastolic dysfunction, with an excessive rise in end-diastolic pressure leading to pulmonary congestion. Alternatively, exertional symptoms may be a result of the limited ability to increase cardiac output with exercise. More severe exertional dyspnea, with orthopnea, paroxysmal nocturnal dyspnea, and pulmonary edema, reflects various degrees of pulmonary venous hypertension. These are relatively late symptoms in patients with AS, and in current practice, intervention typically is undertaken before this disease stage.

Angina occurs in approximately two thirds of patients with severe AS, approximately 50% of whom have associated significant coronary artery obstruction. It usually resembles the angina observed in patients with coronary artery disease (see Chapters 50 and 54) in that it is commonly precipitated by exertion and relieved by rest. In patients without coronary artery disease, angina results from the combination of the increased oxygen needs of hypertrophied myocardium and reduction of oxygen delivery secondary to the excessive compression of coronary vessels. In patients with coronary artery disease, angina is caused by a combination of epicardial coronary artery obstruction and the oxygen imbalance characteristic of AS. Very rarely, angina results from calcific emboli to the coronary vascular bed.

Syncope most commonly is caused by the reduced cerebral perfusion that occurs during exertion when arterial pressure declines consequent to systemic vasodilation in the presence of a fixed cardiac output. Syncope also has been attributed to malfunction of the baroreceptor mechanism in severe AS (see Chapter 89), as well as to a vasodepressor response to a greatly elevated LV systolic pressure during exercise. Premonitory symptoms of syncope are common. Exertional hypotension also may be manifested as “graying-out spells” or dizziness on effort. Syncope at rest may be caused by transient AF with loss of the atrial contribution to LV filling, which causes a precipitous decline in cardiac output, or to transient atrioventricular block caused by extension of the calcification of the valve into the conduction system.

Other late findings in patients with isolated AS include AF, pulmonary hypertension, and systemic venous hypertension. Although AS may be responsible for sudden death (see Chapter 39), this usually occurs in patients who had previously been symptomatic.

Gastrointestinal bleeding may develop in patients with severe AS, often associated with angiodysplasia (most commonly of the right colon) or other vascular malformations. This complication arises from shear stress–induced platelet aggregation with a reduction in high-molecular-weight multimers of von Willebrand factor and increases in proteolytic subunit fragments.³⁷ These abnormalities correlate with the severity of AS and are correctable by AVR.

An increased risk of infective endocarditis has been documented in patients with aortic valve disease, particularly in younger patients with a bicuspid valve (see Chapter 64). Cerebral emboli resulting in stroke or transient ischemic attacks may be caused by microthrombi on thickened bicuspid valves. Calcific AS rarely may cause embolization of calcium to various organs, including the heart, kidneys, and brain.

Physical Examination. The key features of the physical examination in patients with AS are palpation of the carotid upstroke, evaluation of the systolic murmur, assessment of splitting of the second heart sound (S_2), and examination for signs of heart failure (see Chapter 11).

The carotid upstroke directly reflects the arterial pressure waveform. The expected finding with severe AS is a slow-rising, late-peaking, low-amplitude carotid pulse, the parvus and tardus carotid impulse (Fig. 63-5). When present, this finding is specific for severe AS. However, many adults with AS have concurrent conditions, such as AR or systemic hypertension, that affect the arterial pressure curve and the carotid impulse. Thus an apparently normal carotid impulse

is not reliable for excluding the diagnosis of severe AS. Similarly, blood pressure is not a helpful method for evaluation of AS severity. With severe AS, systolic blood pressure and pulse pressures may be reduced. However, in patients with associated AR or in older patients with an inelastic arterial bed, systolic and pulse pressures may be normal or even increased. Also with severe AS, radiation of the murmur to the carotids may result in a palpable thrill or carotid shudder.

The cardiac impulse is sustained and becomes displaced inferiorly and laterally with LV failure. Presystolic distention of the left ventricle (i.e., a prominent precordial a wave) often is visible and palpable. A hyperdynamic left ventricle suggests concomitant AR and/or MR. A systolic thrill usually is best appreciated when the patient leans forward during full expiration. It is palpated most readily in the second right intercostal space or suprasternal notch and frequently is transmitted along the carotid arteries. A systolic thrill is specific, but not sensitive, for severe AS.

Auscultation. The ejection systolic murmur of AS typically is late-peaking and heard best at the base of the heart, with radiation to the carotids (see Fig. 63-5). Cessation of the murmur before A_2 is helpful in differentiation from a pansystolic mitral murmur. In patients with calcified aortic valves, the systolic murmur is loudest at the base of the heart, but high-frequency components may radiate to the

FIGURE 63-5 Relationship between left ventricular (LV) and aortic (Ao) pressures and the Doppler aortic stenosis velocity curve (red). The pressure difference between the left ventricle and aorta in systole is four times the velocity squared (the Bernoulli equation). Thus a maximum velocity (Vmax) of 4.3 m/sec corresponds to a maximum LV-to-aortic pressure difference of 74 mm Hg and a mean systolic gradient of 44 mm Hg. On physical examination, the slow rate of rise and delayed peak in the carotid pulse (or parvus and tardus) matches the contour of the aortic pressure waveform. The murmur corresponds to the Doppler velocity curve with a harsh crescendo-decrescendo late-peaking systolic murmur, best heard at the aortic region (upper right sternal border). Often, a soft, high-pitched diastolic decrescendo murmur of AR also can be appreciated.

apex—the so-called Gallavardin phenomenon, in which the murmur may be so prominent that it is mistaken for the murmur of MR. In general, a louder and later-peaking murmur indicates more severe stenosis. However, although a systolic murmur of grade 3 intensity or greater is relatively specific for severe AS, this finding is insensitive, and many patients with severe AS have only a grade 2 murmur. High-pitched decrescendo diastolic murmurs secondary to AR are common in many patients with dominant AS.

Splitting of the second heart sound is helpful in excluding the diagnosis of severe AS because normal splitting implies the aortic valve leaflets are flexible enough to create an audible closing sound (A_2). With severe AS, S_2 may be single, because calcification and immobility of the aortic valve make A_2 inaudible, closure of the pulmonic valve (P_2) is buried in the prolonged aortic ejection murmur, or prolongation of LV systole makes A_2 coincide with P_2 . Paradoxical splitting of S_2 , which suggests associated left bundle branch block or LV dysfunction, also may occur. Thus in older adults, normal splitting of S_2 indicates a low likelihood of severe AS. The first heart sound (S_1) is normal or soft, and a fourth heart sound (S_4) is prominent, presumably because atrial contraction is vigorous and the mitral valve is partially closed during presystole.

In young patients with congenital AS (see Chapter 62), the flexible valve may result in an accentuated A_2 so that S_2 may be normally split, even with severe valve obstruction. In addition, an aortic ejection sound may be audible because of the halting upward movement of the aortic valve. Like an audible A_2 , this sound is dependent on mobility of the valve cusps and disappears when they become severely calcified. Thus it is common in children and young adults with congenital AS but is rare in adults with acquired calcific AS and rigid valves.

When the left ventricle fails and stroke volume falls, the systolic murmur of AS becomes softer; rarely, it disappears altogether. The slow rise in the arterial pulse is more difficult to recognize. Stated simply, with LV failure, the clinical picture changes from one of typical AS to that of severe LV failure with a low cardiac output. Thus occult AS may be a cause of intractable heart failure, and severe AS should be ruled out by echocardiography in patients with heart failure of unknown cause because operative treatment may be lifesaving and result in substantial clinical improvement.

Dynamic Auscultation. The intensity of the systolic murmur varies from beat to beat when the duration of diastolic filling varies, as in AF or after a premature contraction. This characteristic is helpful in differentiating AS from MR, in which the murmur usually is unaffected. The murmur of valvular AS is augmented by squatting, which increases stroke volume. It is reduced in intensity during the strain of the Valsalva maneuver and on standing, both of which reduce transvalvular flow.

Echocardiography

Echocardiography (see Chapter 14) is the standard approach for evaluating and following patients with AS and selecting them for operation (see Figs. 14-47 to 14-50). Echocardiographic imaging allows accurate definition of valve anatomy, including the cause of AS and the severity of valve calcification, and sometimes allows direct imaging of the orifice area using three-dimensional imaging.^{22,38-40} Echocardiographic imaging also is invaluable for the evaluation of LV hypertrophy and systolic function, with calculation of ejection fraction, measurement of aortic sinus dimensions and detection of associated mitral valve disease.³⁹

Doppler echocardiography allows measurement of transaortic jet velocity, which is the most useful measure for following disease severity and predicting clinical outcome. The stenotic orifice area is calculated using the continuity equation, and mean transaortic pressure gradient is calculated using the modified Bernoulli equation (see Fig. 14-49).^{39,40} Both valve area and pressure gradient calculations from Doppler data have been well validated compared with invasive hemodynamics and in terms of their ability to predict clinical outcome. However, the accuracy of these measures requires an experienced laboratory with meticulous attention to technical details.

The combination of pulsed, continuous-wave and color flow Doppler echocardiography is helpful in detecting and determining the severity of AR (which coexists in approximately 75% of patients with predominant AS) and in estimating pulmonary artery pressure. In some patients, additional measures of AS severity may be

necessary, such as correction for poststenotic pressure recovery or three-dimensional transesophageal imaging of valve anatomy (see Chapter 14). Evaluation of AS severity is affected by the presence of systemic hypertension so that reevaluation after blood pressure control may be necessary.⁴¹ In patients with LV dysfunction and low cardiac output, assessing the severity of AS can be enhanced by assessing hemodynamic changes during dobutamine infusion (see later).

Other Diagnostic Evaluation Modalities

Electrocardiography. The principal electrocardiographic change is LV hypertrophy (see Chapter 12), which is found in approximately 85% of patients with severe AS. The absence of LV hypertrophy does not exclude the presence of critical AS, and the correlation between the absolute electrocardiographic voltages in precordial leads and the severity of obstruction is poor in adults but good in children with congenital AS. T wave inversion and ST-segment depression in leads with upright QRS complexes are common. Evidence of left atrial enlargement is seen in more than 80% of patients with severe isolated AS. AF occurs in only 10% to 15% of patients with AS. The extension of calcific infiltrates from the aortic valve into the conduction system may cause various forms and degrees of atrioventricular and intraventricular block in 5% of patients with calcific AS. Such conduction defects are more common in patients who have associated mitral annular calcification.

Radiography. On the chest radiograph (see Fig. 15-13), the heart usually is of normal size or slightly enlarged, with a rounding of the LV border and apex, unless regurgitation or LV failure is present and causes substantial cardiomegaly. Dilation of the ascending aorta is a common finding, particularly in patients with a bicuspid aortic valve. Calcification of the aortic valve is found in almost all adults with hemodynamically significant AS but is rarely visible on the chest radiograph, although readily detected by fluoroscopy or cardiac CT (see Fig. 18-25). The left atrium may be mildly enlarged in patients with severe AS, and radiologic signs of pulmonary venous hypertension also may be noted. However, when left atrial enlargement is marked, the presence of associated mitral valvular disease should be suspected (see Fig. e15-4).

Cardiac Catheterization and Angiography. In almost all patients, the echocardiographic examination provides the important hemodynamic information required for patient management, and cardiac catheterization is now recommended only when noninvasive tests are inconclusive, when clinical and echocardiographic findings are discrepant, and for coronary angiography before surgical intervention.^{1,2,42,43} Hemodynamic or echocardiographic assessment of AS severity at rest and with dobutamine is reasonable when AS is associated with low cardiac output and impaired LV function (see later).

Advanced Imaging Modalities. In addition to assessing aortic valve calcification, CT (see Chapter 18) is useful for evaluating aortic dilation in patients with evidence of aortic root disease by echocardiography or chest radiography. Measurement of aortic dimensions at several levels, including the sinuses of Valsalva, sinotubular junction, and ascending aorta, is necessary for clinical decision making and surgical planning.

Cardiac magnetic resonance (CMR) is useful for assessing LV volume, function, and mass, especially in settings in which this information cannot be obtained readily from echocardiography (see Chapter 17).⁴⁴ Aortic valve anatomy (see Fig. 17-27) and AS severity also can be assessed by CMR, although this approach is not widely used.⁴⁵

Positron emission tomography (PET) has been used to visualize the location and severity of inflammation and calcification in experimental models and in humans with calcific valve disease.^{46,47} The clinical role of this approach has not been evaluated.

Disease Course

Clinical Outcome

ASYMPTOMATIC PATIENTS. The severity of outflow tract obstruction gradually increases over 10 to 15 years, so the clinical course includes a long latent period during which stenosis severity is only mild to moderate and clinical outcomes are similar to those for age-matched normal patients.^{48,49} Of patients with mild valve thickening but no obstruction to outflow (e.g., aortic sclerosis), 16% will have valve obstruction at 1 year of follow-up, but only 2.5% will develop severe valve obstruction at an average of 8 years after the diagnosis

of aortic sclerosis. Disease progression may be related to different factors than initiation of disease.⁵⁰ Factors associated with progression of AS in asymptomatic patients are listed in **Table 63-4**.

Once moderate to severe AS is present, prognosis remains excellent so long as the patient remains asymptomatic.⁵¹ The progressive nature of the disease, however, warrants close follow-up. Although stenosis is on average more severe in symptomatic than in asymptomatic patients, marked overlap is evident in all measures of severity between these two groups. Prospective studies evaluating the rate of progression to symptomatic AS in initially asymptomatic patients are summarized in **Table e63-2**. The strongest predictor of progression to symptoms is the Doppler aortic jet velocity.^{5,52} Survival free of symptoms is 84% at 2 years when jet velocity is less than 3 m/sec, compared with only 21% when jet velocity is greater than 4 m/sec (**Fig. 63-6**). In adults with severe AS (Doppler velocity >4 m/sec), outcome can be further predicted by the magnitude of the Doppler velocity (see **Fig. 63-6B**) and also by the severity of aortic valve calcification.⁵³⁻⁵⁵ In such studies, most events consisted of the development of symptoms prompting AVR and not sudden death in otherwise asymptomatic patients. However, retrospective studies have

reported some cases of sudden death in apparently asymptomatic adults with severe AS.

SYMPTOMATIC PATIENTS. Once even mild symptoms are present, survival is poor unless outflow obstruction is relieved. Survival curves derived from older retrospective studies show that the interval from the onset of symptoms to the time of death is approximately 2 years in patients with heart failure, 3 years in those with syncope, and 5 years in those with angina. More recent series have confirmed this poor prognosis, with an average survival of only 1 to 3 years after symptom onset.⁵⁶ In the PARTNER (Placement of Transcatheter Aortic Valves) study, outcomes were very poor for patients with severe symptomatic AS deemed unsuitable candidates for surgery who were randomly assigned to conventional therapy (e.g., medical therapy without transcatheter valve implantation), with a 1-year mortality of 50.9% and a 2-year mortality of 68%.^{57,58} Among symptomatic patients with severe AS, the outlook is poorest when the left ventricle has failed and the cardiac output and transvalvular gradient both are low. The risk of sudden death is high with symptomatic severe AS, so these patients should be promptly referred for surgical intervention. In patients who do not undergo surgical intervention, recurrent hospitalizations for angina and decompensated heart failure are common, associated with significant consumption of health care resources.⁵⁹

TABLE 63-4 Risk Stratification of Patients with Severe Aortic Stenosis

†Markers of increased risk and/or potential fatality.

BNP = brain natriuretic peptide; EF = ejection fraction; STS = Society of Thoracic Surgeons.

From Lindman BR, Bonow RO, Otto CM: Current management of calcific aortic stenosis. *Circ Res* 113:223, 2013.

Hemodynamic Progression

The average rate of hemodynamic progression is an annual decrease in aortic valve area of 0.12 cm²/year, an increase in aortic jet velocity of 0.32 m/sec/year, and an increase in mean gradient of 7 mm Hg/year. The rate of progression is highly variable, however, and difficult to predict in individual patients. In clinical studies, the factors associated with more rapid hemodynamic progression included older age, more severe leaflet calcification, renal insufficiency, hypertension, smoking, and hyperlipidemia. The role of genetic factors remains unclear.

Because of the variability in hemodynamic severity at symptom onset and because many patients fail to recognize symptom onset resulting from the insidious rate of disease progression, both exercise testing (see **Table 63-4**) and serum brain natriuretic peptide (BNP) levels²⁴ have been evaluated as measures of disease progression and predictors of symptom onset. Exercise testing monitored by a physician is safe in adults with severe AS when symptom status is unclear,^{60,61} and patients who develop symptoms or exhibit a decrease in blood pressure with exertion should be considered to have symptomatic disease.^{62,63} An elevated BNP level may be helpful when symptoms

FIGURE 63-6 **A**, Natural history as reflected by event-free survival in asymptomatic patients with AS. Initial aortic jet velocity (Vmax) stratifies patients according to the likelihood that symptoms requiring valve replacement will develop over time. **B**, Outcomes with very severe AS. Kaplan-Meier event-free survival rate for patients with a peak aortic jet velocity of 4.0 m/sec or greater. In both **A** and **B**, most “events” consisted of the onset of symptoms warranting aortic valve replacement. TABLE e63-2 Clinical Outcomes in Prospective Studies of Asymptomatic Aortic Stenosis in Adults

STUDY	NO. OF PATIENTS	SEVERITY OF AORTIC STENOSIS	AGE (YEARS)	MEAN FOLLOW-UP	EVENT-FREE SURVIVAL WITHOUT SYMPTOMS
Kelly et al, 1988	51	Vmax >3.6 m/sec	63 ± 8	5-25 months	Overall: 59% at 15 months
Pellikka et al, 1990	113	Vmax ≥4.0 m/sec	40-94	20 months	Overall: 86% at 1 year, 62% at 2 years
Kennedy et al, 1991	66	AVA = 0.7-1.2 cm ²	67 ± 10	35 months	Overall: 59% at 4 years
Otto et al, 1997	123	Vmax >2.6 m/sec	63 ± 16	2.5 ± 1.4 years	Overall: 93% ± 5% at 1 year, 62% ± 8% at 3 years; 26% ± 10% at 5 years Subgroups: Vmax <3 m/sec: 84% ± 16% at 2 years Vmax 3-4 m/sec: 66% ± 13% at 2 years Vmax >4 m/sec: 21% ± 18% at 2 years
Rosenhek et al, 2000	128	Vmax >4.0 m/sec	60 ± 18	22 ± 18 months	Overall: 67% ± 5% at 1 year, 56% ± 55% at 2 years, 33% ± 5% at 4 years Subgroups: No or mild Ca ²⁺ : 75% ± 9% at 4 years Moderate-severe Ca ²⁺ : 20% ± 5% at 4 years
Rosenhek et al, 2004	176	Vmax 2.5-3.9 m/sec LVEF >50%	58 ± 19	48 ± 19 months	95% at 1 year 75% at 2 years 60% at 5 years
Pellikka et al, 2005	622	Vmax ≥4.0 m/sec	72 ± 11	5.4 ± 4.0 years	Overall: 82% at 1 year, 67% at 2 years, 33% at 5 years
Rossebo et al, 2008	1873	Vmax 2.5-4.0 m/sec	68 ± 9	52 months (median)	Event-free survival 65% at 5 years No effect of statin therapy on major CV events
Lancellotti et al, 2010	163	AVAi ≤0.6 cm ² /m ² No AS symptoms LVEF ≥55%	70 ± 10	20 ± 19 months	Event-free survival 50% at 2 years, 44% at 4 years Multivariate predictors of clinical outcome were Vmax ≥4.4 m/sec, LV longitudinal deformation ≤15.9%, valvuloarterial impedance ≥4.9 mm Hg/m ² , LA area ≥12.2 cm ² /m ²
Kang et al, 2010	95	AVA 0.75 cm ² PLUS Vmax ≥4.5 m/sec or ΔP _{mean} ≥50 mm Hg	63 ± 12	50 months	71% ± 5% at 2 years 47% ± 5% at 4 years 28% ± 6% at 6 years Multivariate predictors of survival were Vmax ≥5 m/sec age, male sex, EuroScore, degree of valve calcification
Stewart et al, 2010	183	Vmax >3 m/sec LVEF >50%	70	31 months (median)	Probability of symptom-free survival at 3 years (95% CI) Vmax <3.5 m/sec: 0.72 (0.61-0.84) Vmax 3.5-4.0 m/sec: 0.46 (0.30-0.62) Vmax >4.0 m/sec: 0.32 (0.20-0.44)
Rosenhek et al, 2010	116	Vmax ≥5.0 m/sec	67 ± 15	41 (median)	Vmax 5.0-5.5 m/sec: 43% at 2 years Vmax ≥5.5 m/sec: 25% at 2 years Vmax but not AVA predicted outcome
Jander et al, 2011	435	Low-gradient "severe" AS: AVA <1 cm ² with ΔP _{mean} ≤40 mm Hg	70 ± 9	46 ± 14 months	No difference in event rates between groups Low-gradient "severe" AS, defined as an AVA <1 cm ² with ΔP _{mean} ≤40 mm Hg, was NOT a predictor of clinical outcome
	184	Moderate AS: AVA 1-1.5 cm ² , ΔP _{mean} 25-40 mm Hg	67 ± 9	46 ± 14 months	
Saito et al, 2012	103	AVA <1.0 cm ²	72 ± 11	36 ± 27	AVA index <0.6 cm ² /m ² : 41% at 3 years AVA index ≥0.6 cm ² /m ² : 86% at 3 years Multivariate analysis: AVAi <0.6 cm ² /m ² (HR 2.6; 95% CI 1.1-6.3) Vmax >4.0 m/sec (HR 2.6; 95% CI 1.2-5.8) AVA <0.75 cm ² did NOT predict outcome (mean BSA 1.50 ± 0.15 m ²)

AVA = aortic valve area; BNP = blood natriuretic peptide level (pg/mL); Ca²⁺ = aortic valve calcification; ln = logarithm; Mod = moderate; Vmax = maximum aortic velocity. Data from Kelly TA, Rothbart RM, Cooper CM, et al: Comparison of outcome of symptomatic to asymptomatic patients older than 20 years of age with valvular aortic stenosis. *Am J Cardiol* 61:123,1988; Pellikka PA, Nishimura RA, Bailey KR, Tajik AJ: The natural history of adults with asymptomatic, hemodynamically significant aortic stenosis. *J Am Coll Cardiol* 15:1012, 1990; Kennedy KD, Nishimura RA, Holmes DR, Bailey KR: Natural history of moderate aortic stenosis. *J Am Coll Cardiol* 17:313, 1991; Otto CM, Burwash IG, Legget ME, et al: A prospective study of asymptomatic valvular aortic stenosis: Clinical, echocardiographic, and exercise predictors of outcome. *Circulation* 95:2262, 1997; Rosenhek R, Binder T, Porenta G, et al: Predictors of outcome in severe asymptomatic aortic valve stenosis. *N Engl J Med* 343:611, 2000; Pellikka PA, Sarano ME, Nishimura RA, et al: Outcome of 622 adults with asymptomatic, hemodynamically significant aortic stenosis during prolonged follow-up. *Circulation* 111:3290, 2005; Monin JL, Lancellotti P, Monchi M, et al: Risk score for predicting outcome in patients with asymptomatic aortic stenosis. *Circulation* 120:69, 2009; Rosenhek R, Klar U, Schemper M, et al: Mild and moderate aortic stenosis: Natural history and risk stratification by echocardiography. *Eur Heart J* 25:199, 2004; Pellikka PA, Sarano ME, Nishimura RA, et al: Outcome of 622 adults with asymptomatic, hemodynamically significant aortic stenosis during prolonged follow-up. *Circulation* 111:3290, 2005; Rossebo AB, Pedersen TR, Boman K, et al: Intensive lipid lowering with simvastatin and ezetimibe in aortic stenosis. *N Engl J Med* 359:1343, 2008; Lancellotti P, Donal E, Magne J, et al: Risk stratification in asymptomatic moderate to severe aortic stenosis: The importance of the valvular, arterial and ventricular interplay. *Heart* 96:1364, 2010; Kang DH, Park SJ, Rim JH, et al: Early surgery versus conventional treatment in asymptomatic very severe aortic stenosis. *Circulation* 121:1502, 2010; Stewart RA, Kerr AJ, Whalley GA, et al: Left ventricular systolic and diastolic function assessed by tissue Doppler imaging and outcome in asymptomatic aortic stenosis. *Eur Heart J* 31:2216, 2010; Rosenhek R, Zilberszac R, Schemper M, et al: Natural history of very severe aortic stenosis. *Circulation* 121:151, 2010; Jander N, Minners J, Holme I, et al: Outcome of patients with low-gradient "severe" aortic stenosis and preserved ejection fraction. *Circulation* 123:887, 2011; Saito T, Muro T, Takeda H, et al: Prognostic value of aortic valve area index in asymptomatic patients with severe aortic stenosis. *Am J Cardiol* 110:93, 2012.

are equivocal or when stenosis severity is only moderate, but the role of BNP monitoring in evaluation of disease progression has not been fully defined.⁶⁴

Medical Management. The most important principle in the management of adults with AS is patient education regarding the disease course and typical symptoms. Patients should be advised to promptly report the development of any symptoms possibly related to AS. Patients with severe AS should be cautioned to avoid vigorous athletic sports and physical activity. Such restrictions do not apply to patients with mild obstruction. Although medical therapy has not been shown to affect disease progression, adults with AS (as with any other adult) should be evaluated and treated for conventional coronary disease risk factors, in accordance with established guidelines.

Echocardiography is recommended for the initial diagnosis and assessment of AS severity, assessment of LV hypertrophy and systolic function, reevaluation in patients with changing signs or symptoms, and reevaluation conducted annually for severe AS, every 1 to 2 years for moderate AS, and every 3 to 5 years for mild AS.^{1,2} Because patients may tailor their lifestyle to minimize symptoms or may ascribe fatigue and dyspnea to deconditioning or aging, they may not recognize early symptoms as important warning signals, although these symptoms often can be elicited by a careful history. Exercise testing may be helpful in apparently asymptomatic patients to detect covert symptoms, limited exercise capacity, or an abnormal blood pressure response.^{60,61} Exercise stress testing should be absolutely avoided in symptomatic patients.

Symptomatic patients with severe AS usually are operative candidates, because medical therapy has little to offer. However, medical therapy may be necessary for patients considered to be inoperable, usually because of comorbid conditions that preclude surgery. Some of these patients may be candidates for transcatheter valve implantation, but others will not be candidates for or will decline this procedure. Although diuretics are beneficial when there is abnormal accumulation of fluid, they must be used with caution because hypovolemia may reduce the elevated LV end-diastolic pressure, lower cardiac output, and produce orthostatic hypotension. ACE inhibitors should be used with caution but are beneficial in treating patients with symptomatic LV systolic dysfunction who are not candidates for surgery and, in fact, have been shown in epidemiologic studies to improve outcomes in patients with AS.³³ They should be initiated at low doses and increased slowly to target doses, avoiding hypotension. Beta-adrenergic blocking agents can depress myocardial function and induce LV failure and generally should be avoided in patients with AS.

AF or atrial flutter occurs in less than 10% of patients with severe AS, perhaps because of the late occurrence of left atrial enlargement in this condition. When such an arrhythmia is observed in a patient with AS, the possibility of associated mitral valvular disease should be considered. When AF occurs, the rapid ventricular rate may cause angina pectoris. The loss of the atrial contribution to ventricular filling and a sudden fall in cardiac output may cause serious hypotension. Therefore AF should be treated promptly, usually with cardioversion. New-onset AF in a previously asymptomatic patient with severe AS may be a marker of impending symptom onset.⁶⁵

Management of concurrent cardiac conditions, such as hypertension and coronary disease, is complicated in patients with asymptomatic AS by the concern that the vasodilatory effects of medications may not be offset by a compensatory increase in cardiac output. Despite this concern, AS patients should receive appropriate treatment for concurrent disease, although medications should be started at low doses and slowly titrated upward, with close monitoring of blood pressure and symptoms. Adults with asymptomatic severe AS can undergo noncardiac surgery and pregnancy, with careful hemodynamic monitoring and optimization of loading conditions. When stenosis is very severe, however, elective AVR before noncardiac surgery or a planned pregnancy may be considered.

Although elevated serum lipids are associated with the presence of aortic valve disease, to date there is no convincing evidence that lipid-lowering therapy affects disease progression.¹⁵ No benefit was seen in a small prospective randomized trial of atorvastatin versus placebo, despite a significant lowering of serum LDL levels, in patients with relatively advanced calcific AS,⁶⁶ and a subsequent prospective study in patients with less severe AS demonstrated only a slight reduction in the rate of progression of AS with rosuvastatin.⁶⁷ The Simvastatin and Ezetimibe for Aortic Stenosis (SEAS) Trial⁶⁸ and the Aortic Stenosis Progression Observation: Measuring Effects of Rosuvastatin (ASTRONOMER) Trial⁶⁹ randomly assigned 1800 and 269 adults,

respectively, with mild to moderate AS to intensive lipid-lowering therapy versus placebo. These studies were adequately powered and showed no improvement in mortality, time to valve replacement, or rate of AS progression in the treatment versus placebo groups. Current interest is focused on other disease pathways in calcific valve disease that may be amenable to medical therapy.^{13,70,71}

Surgical Treatment

Children

In the adolescent or young adult with severe congenital AS, balloon aortic valvotomy is recommended for all symptomatic patients and asymptomatic patients with a transvalvular gradient higher than 60 mm Hg or electrocardiographic ST-segment changes at rest or with exercise.⁷² The same indications are appropriate for surgical intervention, although balloon valvotomy is probably preferable at experienced centers. At surgery, simple commissural incision under direct vision usually leads to substantial hemodynamic improvement with low risk (i.e., mortality rate <1%; [see Chapter 62](#)). Despite the salutary hemodynamic results after percutaneous or surgical valvotomy, the valve is not rendered entirely normal anatomically. The turbulent blood flow through the valve may induce changes leading to further deformation, calcification, development of regurgitation, and restenosis after 10 to 20 years, often necessitating subsequent reoperation and valve replacement.

Adults

AVR is recommended for adults with symptomatic severe AS, even if symptoms are mild. Despite this clear guideline recommendation,^{1,2} many patients with symptomatic AS are not referred appropriately for surgery, even when the operative risk is low.⁴⁷ AVR also is recommended for severe AS with an ejection fraction less than 50% and for patients with severe asymptomatic AS who are undergoing coronary bypass grafting (CABG) or other forms of heart surgery.^{1,2,5} ([Fig. 63-7](#)). In addition, AVR is appropriate for apparently asymptomatic patients with severe AS when exercise testing provokes symptoms or a fall in blood pressure. Outcomes are similar in patients with mixed AS and AR so that standard criteria for intervention are applicable in this patient group.^{73,74} In asymptomatic patients with severe AS and a low operative risk, AVR may be considered when markers of rapid disease progression are present (e.g., severe valve calcification) or when AS is very severe, depending on patient preferences regarding the risk of earlier intervention versus careful monitoring with intervention promptly at symptom onset. Coronary angiography should be performed before valve replacement in most adults with AS.

Surgical AVR is the procedure of choice for relief of outflow obstruction in adults with valvular AS. Surgical repair is not feasible because attempts at débridement of valve calcification have not been successful. Balloon aortic valvotomy has only a modest hemodynamic effect in patients with calcific AS and does not favorably affect long-term outcome. Thus balloon aortic valvotomy is not recommended as an alternate to AVR for calcific AS. In selected cases, balloon valvotomy might be reasonable as a bridge to surgery in unstable patients or as a palliative procedure when surgery is very high risk.

Transcatheter Aortic Valve Implantation

TAVI by a percutaneous or transapical approach offers an alternate approach to treatment of severe AS, particularly in patients with prohibitive surgical risk and also is a reasonable option in patients at very high surgical risk ([see Chapter 56](#)). In Cohort B of the U.S. randomized prospective PARTNER trial, which compared TAVI with medical therapy (including balloon valvotomy) in patients with prohibitive risk for surgical AVR, TAVI resulted in a substantial reduction in rates of death and hospitalization and was associated with significant relief of symptoms.^{57,58} ([Fig. 63-8](#)). The benefit of TAVI was greatest in those with a Society of Thoracic Surgeons (STS) score below 15, in whom surgical AVR often was not possible because of technical limitations to thoracotomy such as a porcelain aorta or radiation-induced heart disease. In patients with a STS score of 15 or higher, outcomes were similar at 2-year follow-up with a mortality rate in excess of 50%, probably as a result of extensive comorbidity in these

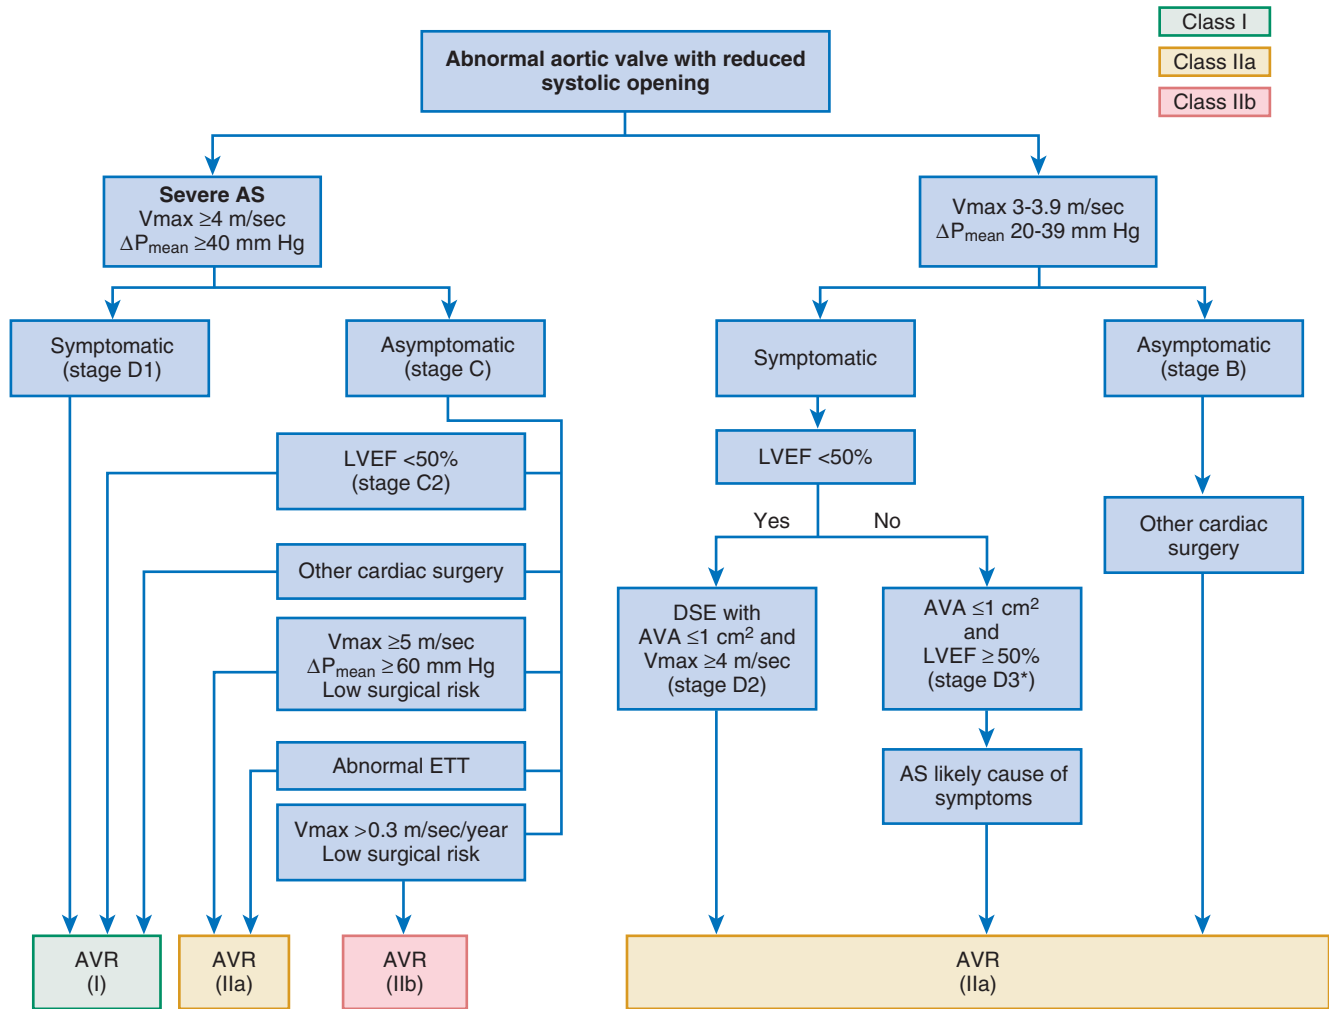

FIGURE 63-7 Management strategy for patients with severe AS. Periodic monitoring is indicated for all patients in whom AVR, by either a surgical or a transcatheter approach, is not yet indicated, including those with asymptomatic AS (stage D or C) and those with low-gradient AS (stage D2 or D3) who do not meet criteria for intervention. *AVR should be considered with stage D3 AS only if valve obstruction is the most likely cause of symptoms, stroke volume index is <35 mL/m², indexed AVA is ≤0.6 cm²/m², and data are recorded when the patient is normotensive (systolic BP <140 mm Hg). AVA = aortic valve area; BP = blood pressure; DSE = dobutamine stress echocardiography; ETT = exercise treadmill test; LVEF = left ventricular ejection fraction; ΔP_{mean} = mean pressure gradient; Vmax = maximum velocity. (From Nishimura RA, Otto CM, Bonow RO, et al: 2014 AHA/ACC guideline for the management of patients with valvular heart disease: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 63:e57: 2014.)

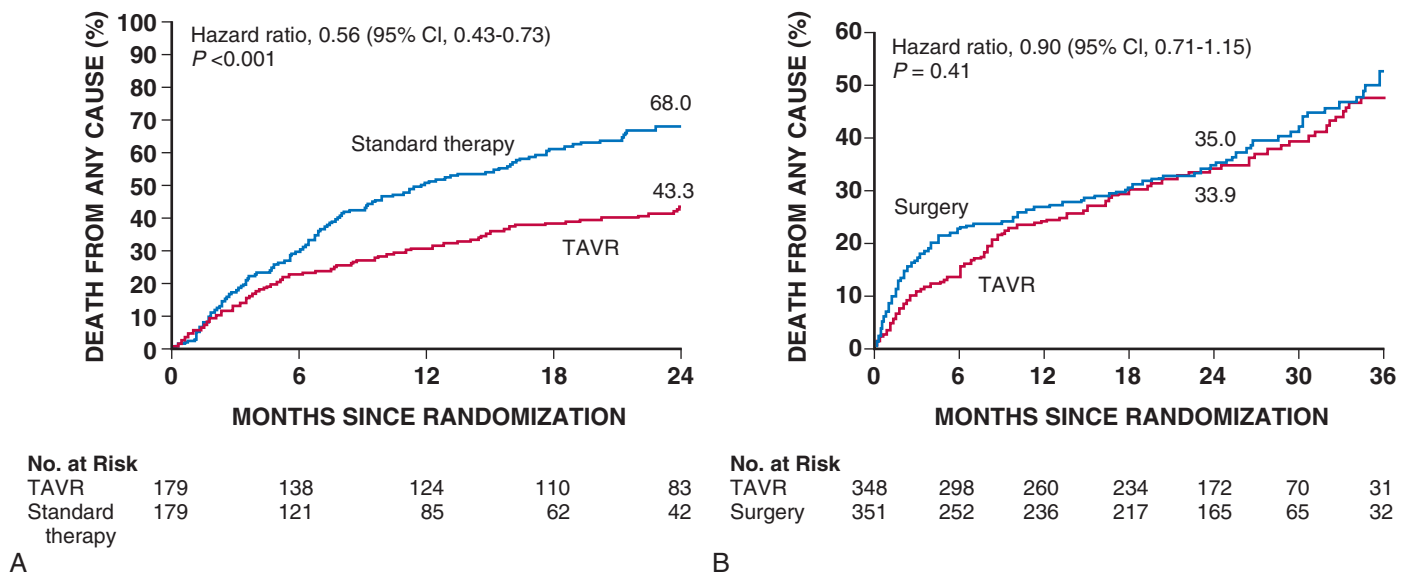

FIGURE 63-8 A, TAVR in inoperable severe symptomatic AS. Kaplan-Meier survival rates are shown for symptomatic patients with severe AS deemed unsuitable candidates for surgery who were managed with conventional therapy (n = 179) versus TAVR (n = 179). **B**, TAVR surgical aortic valve replacement in high-risk patients. Kaplan-Meier survival rates are shown for high-risk patients with severe AS receiving surgical aortic valve replacement therapy (n = 351) versus TAVR (n = 348). TAVR = transcatheter aortic valve replacement. (A, From Makkar RR, Fontana GP, Jilaihawi H, et al: Transcatheter aortic-valve replacement for inoperable severe aortic stenosis. *N Engl J Med* 366:1696, 2012. B, From Kodali SK, Williams MR, Smith CR, et al: Two-year outcomes after transcatheter or surgical aortic-valve replacement. *N Engl J Med* 366:1686, 2012.)

patients. In patients at high, but not prohibitive, surgical risk (PARTNER Cohort A), outcomes with surgical AVR and with TAVI were similar at 2 years (see Fig. 63-8B), although paravalvular regurgitation was more common after TAVI (see Fig. 14-61) and a higher prevalence of stroke was noted in the TAVI group.^{75,76} The efficacy of TAVI in the PARTNER trial is mirrored by clinical results reported in large TAVI registries supporting the use of TAVI in patients at high or prohibitive surgical risk.⁷⁷⁻⁸¹ Long-term durability of the TAVI bioprosthetic valves has not been adequately defined, so at present, conventional surgical AVR remains the procedure of choice in patients at low or intermediate surgical risk.⁸²⁻⁸⁵

Aortic Stenosis with Left Ventricular Dysfunction. Surgical risk is higher in patients with impaired LV function (ejection fraction <35%).^{23,86,87} Their prognosis, however, is extremely poor without operation; overall survival is improved with AVR, and many patients in this group have significant clinical and functional recovery after AVR. In general, then, AVR should be offered to these patients. Even octogenarians with LV dysfunction can have improved survival after AVR, although their operative risks are higher. Exceptions are patients with advanced congestive heart failure or LV dysfunction that can be related to previous myocardial infarction rather than to AS. In acutely ill patients with decompensated heart failure, nitroprusside has been reported to be safe and effective for rapidly improving hemodynamic status and may be used in bridging critically ill patients to AVR. Small nonrandomized studies suggest that TAVI might be considered for treatment of severe AS with significant LV systolic dysfunction, but further evaluation of this approach is needed.⁸⁸⁻⁹⁰

Aortic Stenosis with Low Gradient and Low Cardiac Output. Patients with critical AS, severe LV dysfunction, and low cardiac output (and hence a low transvalvular pressure gradient) often create diagnostic dilemmas for the clinician because their clinical presentation and hemodynamic data may be indistinguishable from those of patients with a dilated cardiomyopathy and a calcified valve that is not stenotic.^{40,91} Low-flow, low-gradient AS is defined as a valve area of 1.0 cm² or smaller, with an aortic velocity of less than 4.0 m/sec or mean gradient of 40 mm Hg or less (see Table 63-3). Most often, low-gradient low-flow AS occurs in patients with a low ejection fraction (<50%). In this situation, severe AS can be distinguished from moderate AS with primary LV dysfunction based on the changes in valve hemodynamics during transient increases in flow, usually by increasing cardiac output with dobutamine (Fig. 63-9) (see Chapter 14).⁹¹⁻⁹³ Severe AS is present if there is an increase in aortic velocity to at least 4 m/sec at any flow rate, with a valve area that remains less than 1.0 cm²; AS is not severe if the valve area is more than 1.0 cm².²² Dobutamine echocardiography also provides evidence of myocardial contractile reserve (an increase in stroke volume or ejection fraction >20% from baseline), which is an important predictor of operative risk, improvement in LV function, and survival after AVR in these patients. However, even in patients with a lack of contractile reserve, AVR should be considered if the mean gradient is greater than 20 mm Hg, because survival after AVR is better (roughly 50% at 5 years) than with medical therapy.^{86,87}

Low-flow, low-gradient severe AS also can occur with a normal LV ejection fraction (see Table 63-3), typically in elderly patients with a small hypertrophied left ventricle or those with concurrent hypertension. Despite a normal ejection fraction, transaortic volume flow rate is low (<35 mL/m²) because of the small LV size. Distinguishing true severe AS from moderate AS is challenging in this setting—many of these patients have a small body size and only moderate AS, with outcomes similar to those in other adults with moderate AS, and others have severe AS with a poor outcome without relief of AS.⁹⁴⁻⁹⁷ In the patient with possible low-flow low-output severe AS and a normal LV ejection fraction, clinical decision making is challenging but is assisted by objective evaluation of patient symptoms, calculation of indexed valve area, evaluation of valve hemodynamics after treatment of hypertension, and visualization of valve anatomy and calcification severity.⁹⁸

Very Severe Asymptomatic Aortic Stenosis. Management of very severe asymptomatic AS is controversial. The likelihood of symptom onset increases as AS severity increases^{53,99}; symptom onset occurs within 3 years in approximately 50% of patients with an aortic velocity between 4 and 5 m/sec, 67% of patients with an aortic velocity between 5.0 and 5.5 m/sec, and 89% of patients with an aortic velocity greater than 5.5 m/sec (see Fig. 63-6B).⁵³ Other clinical factors predictive of symptom onset include an elevated serum BNP level, moderate to severe valve calcification, a rapid rate of progression

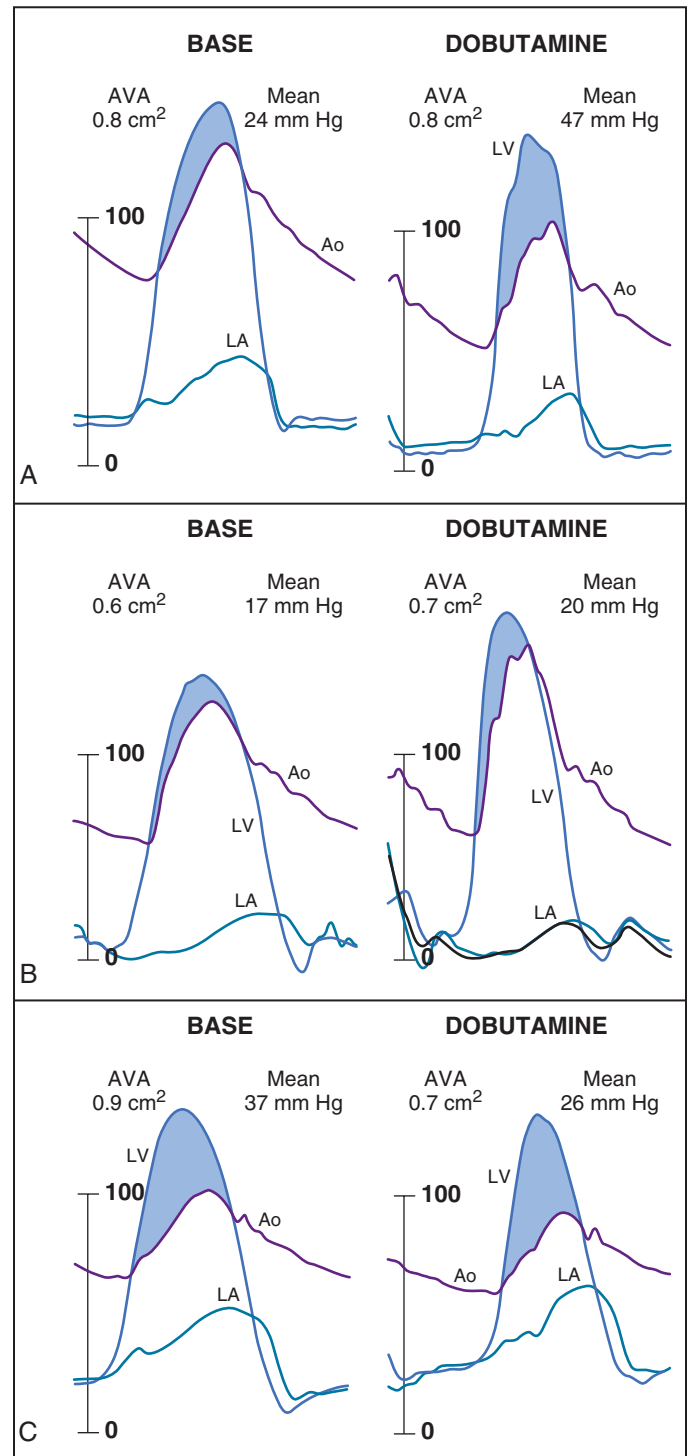

FIGURE 63-9 Hemodynamic tracings from three patients with left ventricular dysfunction, low cardiac output, and low aortic valve gradient, demonstrating three different responses to dobutamine. **A**, Increase in cardiac output and in mean aortic valve gradient from 24 to 47 mm Hg. Aortic valve area (AVA) remained 0.8 cm². This patient underwent successful valve replacement. **B**, Increase in cardiac output and minimal increase in mean pressure gradient from 17 to 20 mm Hg. The final calculated aortic valve area was 0.7 cm². The patient was found to have only minimal AS at the time of surgery. **C**, No change in cardiac output, with decrease in mean pressure gradient from 37 to 26 mm Hg, occurred in response to dobutamine. The test was terminated because of hypotension. The patient was found to have severe AS at the time of surgery. Ao = aortic; LA = left atrial. (From Nishimura RA, Grantham A, Connolly HM, et al: Low-output, low-gradient aortic stenosis in patients with depressed left ventricular systolic function: The clinical utility of the dobutamine challenge in the catheterization laboratory. *Circulation* 106:809, 2002.)

of AS severity, reduced LV longitudinal strain, myocardial fibrosis, and pulmonary hypertension.^{5,40,54,100} Nonrandomized retrospective studies have raised the question of whether intervention before symptom onset might be appropriate in these patients.^{101,102} However, the morbidity and mortality of earlier intervention and prosthetic valve issues, such as durability, hemodynamics, and anticoagulation, must be balanced against a watchful waiting approach in each patient in the absence of prospective randomized clinical trials.¹⁰³

Results

Successful replacement of the aortic valve results in substantial clinical and hemodynamic improvement in patients with AS, AR, or combined lesions. In patients without frank LV failure, the operative risk ranges from 2% to 5% in most centers,¹⁰⁴ and in patients younger than 70 years, the operative risk has been reported to be as low as 1%. The STS National Database Committee reported an overall operative mortality rate of 3.2% in 67,292 patients undergoing isolated AVR and 5.6% in 66,074 patients undergoing AVR and CABG (Table 63-5).^{105,106} Risk factors associated with a higher mortality rate include a high New York Heart Association (NYHA) functional class, impairment of LV function, advanced age, and the presence of associated coronary artery disease. The 30-day mortality rate also is significantly related to the number of AVR procedures performed at each hospital. The 10-year actuarial survival rate of hospital survivors in surgically treated patients is approximately 85%.^{107,108} Risk factors for late death include higher preoperative NYHA functional class, advanced age, concomitant untreated coronary artery disease, preoperative impaired LV function, preoperative ventricular arrhythmias, and associated significant AR.¹⁰⁹⁻¹¹²

Although age is a determinant of risk, there is increasing experience at most surgical centers in performing AVR in symptomatic patients older than 70 or even 80 years of age with calcific AS.^{113,114} The results of AVR often are satisfactory in this age group, with improved quality of life and survival (see Chapter 76). Surgical risk and postoperative morbidity are related to the higher prevalence of comorbid conditions in older patients, rather than to age per se.^{107,115} Medicare data from the past decade indicate that the 30-day mortality after surgical AVR in patients 65 years and older in the United States has decreased, from 7.6% in 1999 to 4.2% in 2011, with the most marked decrease in patients 85 years and older, in whom the 30-day mortality has decreased from 12.3% to 5.8%.¹¹⁶ Therefore advanced age should not be considered a contraindication to operation.¹¹⁷ Particular attention must be directed to the adequacy of hepatic, renal, and pulmonary functions in these patients.

Symptoms of pulmonary congestion (exertional dyspnea) and of myocardial ischemia (angina pectoris) are relieved in almost all patients, and most patients will exhibit an improvement in exercise

tolerance, even if it was only mildly reduced before surgery. Hemodynamic results of AVR also are impressive; elevated end-diastolic and end-systolic volumes show significant reduction. Impaired ventricular performance returns to normal more frequently in patients with AS than in those with AR or MR. However, the finding that the strongest predictor of postoperative LV dysfunction is preoperative dysfunction suggests that patients should, if possible, be operated on before LV function becomes seriously impaired. The increased LV mass is reduced toward (but not to) normal within 18 months after AVR in patients with AS, with further reduction over the next several years. Coronary flow reserve and diastolic function also demonstrate considerable improvement after AVR. However, interstitial fibrosis regresses more slowly than myocyte hypertrophy, so that diastolic dysfunction may persist for years after successful valve replacement.

When operation is carried out in patients with critical AS, frank LV failure, depressed ejection fraction, or low cardiac output (and hence a reduced transaortic pressure gradient), the operative risk is higher, and the mortality rate ranges from 8% to 20%, depending on the skill of the surgical team and the severity of heart failure. Obviously, performing surgery before heart failure develops is desirable, but emergency operation, even in patients with severe heart failure, is sometimes lifesaving. In patients with AS and obstructive coronary artery disease—a relatively common combination—AVR and myocardial revascularization should be performed together. Although the risk of AVR is increased when accompanied by CABG (see Table 63-5), the surgical risk increases even more when severe coronary artery disease is left untreated. The ability to avoid serious myocardial ischemia in the perioperative period is a major factor that has served to reduce operative mortality in these patients. Characteristics of patients that have been shown to increase the risk of AVR, as reported in different series, are shown in Table 63-4. TAVI now represents an important treatment option in many such patients.

Aortic Regurgitation Causes and Pathology

AR may be caused by primary disease of the aortic valve leaflets and/or the wall of the aortic root¹¹⁸ (Fig. 63-10). Among patients with isolated AR who undergo valve replacement, the percentage with aortic root disease has been increasing steadily during the past few decades; it now represents the most common cause and accounts for more than 50% of all such patients in some series.

Valvular Disease. Primary valvular causes of AR include the following: calcific AS in older patients, in whom some degree (usually mild) of AR is present (in 75% of patients); infective endocarditis (see Chapter 64), in which the infection may destroy or cause perforation

TABLE 63-5 Operative Mortality Rates Following Valve Replacement and Repair (2002-2006 STS Database)

OPERATIVE CATEGORY	NUMBER	OPERATIVE MORTALITY (%)	CVA (%)	RENAL FAILURE (%)	PROLONGED VENTILATION (%)	REOPERATION (%)	ANY ADVERSE EVENT (%)	PROLONGED LENGTH OF STAY (%)
AVR	67,292	3.2	1.5	4.1	10.9	8.0	17.4	7.9
AVR + CABG	66,074	5.6	2.7	7.6	17.6	10.7	26.3	12.7
MVR	21,229	5.7	2.1	6.4	18.9	11.5	26.7	15.3
MVR + CABG	13,663	11.6	3.7	13.6	32.7	16.6	43.2	24.0
MV repair	21,238	1.6	1.4	2.6	7.3	6.3	12.7	5.5
MV repair + CABG	21,924	7.4	3.1	10.3	25.0	12.6	33.5	17.8

Endpoint definitions: Operative mortality = death during hospitalization or within 30 days of valve surgery. Other endpoints are during initial hospitalization for valve surgery: CVA = permanent stroke (neurologic deficit persisting >72 hr); renal failure = new need for dialysis, increase in serum creatinine level to >2.0 mg/dL or increase to twice preoperative baseline; prolonged ventilation = need for ventilatory support >24 hours postoperatively; reoperation = reoperation during initial hospitalization; any adverse event = any of the above endpoints plus deep sternal wound infection (occurred in <1%); prolonged length of stay = postoperative hospitalization >14 days.

CVA = stroke; MV = mitral valve; MVR = mitral valve replacement.

From Shahian DM, O'Brien SM, Filardo G, et al: *The Society of Thoracic Surgeons 2008 cardiac surgery risk models: Part 3—valve plus coronary artery bypass grafting surgery*. *Ann Thorac Surg* 88:S43, 2009; and O'Brien SM, Shahian DM, Filardo G, et al: *The Society of Thoracic Surgeons 2008 cardiac surgery risk models: Part 2—isolated valve surgery*. *Ann Thorac Surg* 88:S23, 2009.

FIGURE 63-10 Diagram of various causes of pure AR. A = anterior; AMVL = anterior mitral valve leaflet; Ca^{2+} = calcification; L = left coronary cusp; N = noncoronary cusp; P = posterior; R = right coronary cusp; VSD = ventricular septal defect. (From Waller BF: Rheumatic and nonrheumatic conditions producing valvular heart disease. *Cardiovasc Clin* 16:30, 1986.)

of a leaflet, or the vegetations may interfere with proper coaptation of the cusps; and trauma that results in a tear of the ascending aorta, in which loss of commissural support can cause prolapse of an aortic cusp. Although the most common complication of a congenitally bicuspid valve in adults is stenosis, incomplete closure and/or prolapse of a bicuspid valve may also cause isolated regurgitation or a combination of stenosis and regurgitation.⁴ Rheumatic fever remains a common cause of primary disease of the aortic valve that leads to regurgitation. The cusps become infiltrated with fibrous tissues and retract a process that prevents cusp apposition during diastole; this usually leads to regurgitation into the left ventricle through a defect in the center of the valve (see Fig. 63-2C). The associated fusion of the commissures may restrict the opening of the valve, resulting in combined AS and AR; some associated mitral valve involvement is also common. Progressive AR may occur in patients with a large ventricular septal defect, as well as in patients with membranous subaortic stenosis (see Chapter 62) and as a complication of percutaneous aortic balloon valvotomy. Progressive regurgitation also may occur in patients with

myxomatous proliferation of the aortic valve. An increasingly common cause of valvular AR is structural deterioration of a bioprosthetic valve.

Less common causes of AR include various forms of congenital AR, such as unicommissural and quadricuspid valves, or rupture of a congenitally fenestrated valve, particularly in the presence of hypertension. Other less common causes of AR occur in association with systemic lupus erythematosus, rheumatoid arthritis, ankylosing spondylitis, Jaccoud arthropathy, Takayasu disease, Whipple disease, Crohn disease, and, in the past, the use of certain anorectic drugs. Isolated congenital AR is an uncommon lesion on necropsy studies but, when present, is usually associated with a bicuspid valve.

Aortic Root Disease. AR secondary to marked dilation of the ascending aorta is now more common than primary valve disease in patients undergoing AVR for isolated AR (see Chapter 57).¹¹⁸ The conditions responsible for aortic root disease include age-related (degenerative) aortic dilation, cystic medial necrosis of the aorta (either isolated or associated with classic Marfan syndrome), aortic dilation related to bicuspid valves,^{4,119} aortic dissection, osteogenesis

imperfecta, syphilitic aortitis, ankylosing spondylitis, Behçet syndrome, psoriatic arthritis, arthritis associated with ulcerative colitis, relapsing polychondritis, reactive arthritis, giant cell arteritis, and systemic hypertension, as well as exposure to some appetite-suppressant drugs.¹²⁰

When the aortic annulus becomes greatly dilated, the aortic leaflets separate and AR may ensue. Dissection of the diseased aortic wall may occur and aggravate the AR. Dilation of the aortic root also may have secondary effects on the aortic valve because dilation causes tension and bowing of the individual cusps, which may thicken, retract, and become too short to close the aortic orifice. This defect leads to intensification of the AR, further dilating the ascending aorta and leading to a vicious circle in which, as is the case for MR, regurgitation leads to regurgitation. AR, regardless of its cause, produces dilation and hypertrophy of the left ventricle, dilation of the mitral valve ring, and sometimes hypertrophy and dilation of the left atrium. Endocardial pockets frequently develop in the LV cavity at sites of impact of the regurgitant jet.

Chronic Aortic Regurgitation

Pathophysiology

In contrast with MR, in which a fraction of the LV stroke volume is ejected into the low-pressure left atrium, in AR the entire LV stroke volume is ejected into a high-pressure chamber (i.e., the aorta), although the low aortic diastolic pressure does facilitate ventricular emptying during early systole (Fig. 63-11). In MR, especially acute MR, the reduction of wall tension (i.e., reduced afterload) allows more complete systolic emptying; in AR, the increase in LV end-diastolic volume (i.e., increased preload) provides hemodynamic compensation.

Severe AR may occur with a normal effective forward stroke volume and a normal ejection fraction ([forward plus regurgitant stroke volume]/[end-diastolic volume]), together with an elevated LV end-diastolic volume, pressure, and stress¹¹⁸ (Fig. 63-12). In accord

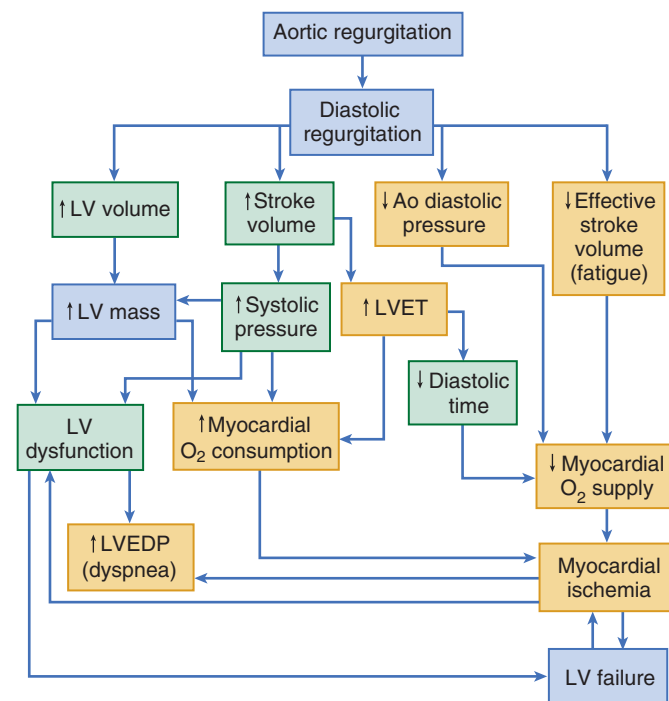

FIGURE 63-11 Pathophysiology of AR. The regurgitation results in an increased LV volume, increased stroke volume, increased aortic (Ao) systolic pressure, and decreased effective stroke volume. Increased LV volume results in an increased LV mass, which may lead to LV dysfunction and failure. Increased LV stroke volume increases systolic pressure and prolongation of LV ejection time (LVET). Increased LV systolic pressure results in a decrease in diastolic time. Decreased diastolic time (myocardial perfusion time), diastolic aortic pressure, and effective stroke volume lead to reduced myocardial O₂ supply. Increased myocardial O₂ consumption and decreased myocardial O₂ supply produce myocardial ischemia, which further impairs LV function. LVEDP = LV end-diastolic pressure. (From Boudoulas H, Gravanis MB: Valvular heart disease. In Gravanis MB [ed]: Cardiovascular Disorders: Pathogenesis and Pathophysiology. St. Louis, CV Mosby, 1993, p 64.)

with Laplace's law, which indicates that wall tension is related to the product of the intraventricular pressure and radius divided by wall thickness, LV dilation also increases the LV systolic tension required to develop any level of systolic pressure. Thus in AR, there is an increase in preload and afterload. LV systolic function is maintained through the combination of chamber dilation and hypertrophy. This leads to eccentric hypertrophy, with replication of sarcomeres in series and elongation of myocytes and myocardial fibers. In compensated AR, sufficient wall thickening has occurred that the ratio of ventricular wall thickness to cavity radius remains normal. Under these conditions, end-diastolic wall stress is maintained at or returns to normal levels. In AS, by contrast, changes include pressure overload (concentric) hypertrophy with replication of sarcomeres, largely in parallel, and an increased ratio of wall thickness to radius, but with both AR and AS, an increase in interstitial connective tissue is seen. In AR, LV mass usually is greatly increased, often to levels even higher than in isolated AS. As AR persists and increases in severity over time, however, wall thickening fails to keep pace with the hemodynamic load, and end-systolic wall stress rises. At this point, the afterload mismatch results in a decline in systolic function, and the ejection fraction falls (see Fig. 63-12).

Patients with severe chronic AR have the largest end-diastolic volumes of those with any form of heart disease, resulting in so-called cor bovinum. However, end-diastolic pressure is not uniformly elevated (i.e., LV compliance often is increased; see Fig. 63-12). In more severe cases of AR, the regurgitant flow may exceed 20 liters/min, so the total LV output at rest approaches 25 liters/min, a level that can be achieved acutely only by a trained endurance runner during maximal exercise. Thus the adaptive response to gradually increasing, chronic AR permits the ventricle to function as an effective high-compliance pump, handling a large stroke volume, often with little increase in filling pressure. During exercise, peripheral vascular resistance declines and, with an increase in heart rate, diastole shortens and the regurgitation per beat decreases, facilitating an increment in effective (forward) cardiac output without substantial increases in end-diastolic volume and pressure. The ejection fraction and related ejection phase indices are often within normal limits, both at rest and during exercise, even though myocardial function, as reflected in the slope of the end-systolic pressure-volume relationship, is depressed.

LEFT VENTRICULAR FUNCTION. As the left ventricle decompensates, interstitial fibrosis increases, compliance declines, and LV end-diastolic pressure and volume rise (see Fig. 63-12). In advanced stages of decompensation, left atrial, pulmonary artery wedge, pulmonary arterial, right ventricular (RV), and right atrial pressures rise and the effective (forward) cardiac output falls, at first during exercise and then at rest. The normal decline in end-systolic volume or the rise in ejection fraction fails to occur during exercise. Symptoms of heart failure develop, particularly those secondary to pulmonary congestion.

MYOCARDIAL ISCHEMIA. When acute AR is induced experimentally, myocardial oxygen requirements rise substantially, secondary to an increase in wall tension. In patients with chronic severe AR, total myocardial oxygen requirements also are augmented by the increase in LV mass. Because the major portion of coronary blood flow occurs during diastole, when arterial pressure is lower than normal in AR, coronary perfusion pressure is reduced. Studies in experimentally induced AR have shown a reduction in coronary flow reserve, with a change in forward coronary flow from diastole to systole. The result—a combination of increased oxygen demands and reduced supply—sets the stage for the development of myocardial ischemia, especially during exercise. Thus patients with severe AR exhibit a reduction of coronary reserve, which may be responsible for myocardial ischemia and which may in turn play a role in the deterioration of LV function.

Clinical Presentation

The clinical stages of chronic AR are indicated in Table 63-6, demonstrating the progressive nature of the disease.

Symptoms. In chronic severe AR, the left ventricle gradually enlarges while the patient remains asymptomatic.^{118,121} Symptoms of

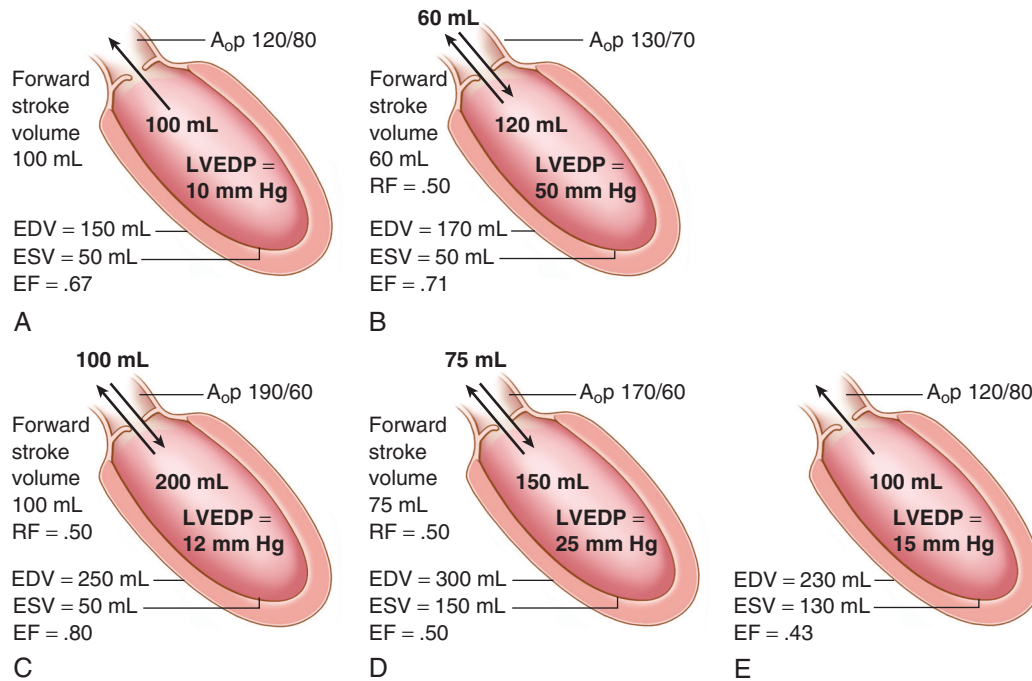

FIGURE 63-12 Hemodynamics of AR. **A**, Normal conditions. **B**, The hemodynamic changes that occur in severe acute AR. Although total stroke volume is increased, forward stroke volume is reduced. LV end-diastolic pressure (LVEDP) rises dramatically. **C**, Hemodynamic changes occurring in chronic compensated aortic regurgitation are shown. Eccentric hypertrophy produces increased end-diastolic volume (EDV), which permits an increase in total, as well as forward, stroke volume. The volume overload is accommodated, and LV filling pressure is normalized. Ventricular emptying and end-systolic volume (ESV) remain normal. **D**, In chronic decompensated AR, impaired LV emptying produces an increase in end-systolic volume and a fall in ejection fraction (EF), total stroke volume, and forward stroke volume. Further cardiac dilation and re-elevation of LV filling pressure occur. **E**, Immediately after valve replacement, preload estimated by EDV decreases, as does filling pressure. ESV also is decreased, but to a lesser extent. The result is an initial fall in EF. Despite these changes, elimination of regurgitation leads to an increase in forward stroke volume, and with time ejection fraction increases. Aop = aortic pressure; RF = regurgitant fraction. (From Carabello BA: Aortic regurgitation: Hemodynamic determinants of prognosis. In Cohn LH, DiSesa VJ [eds]: Aortic Regurgitation: Medical and Surgical Management. New York, Marcel Dekker, 1986, pp 99-101.)

reduced cardiac reserve or myocardial ischemia develop, most often in the fourth or fifth decade of life, and usually only after considerable cardiomegaly and myocardial dysfunction have occurred. The principal manifestations—exertional dyspnea, orthopnea, and paroxysmal nocturnal dyspnea—usually develop gradually. Angina pectoris is prominent late in the course; nocturnal angina may be troublesome and often is accompanied by diaphoresis, which occurs when the heart rate slows and arterial diastolic pressure falls to extremely low levels. Patients with severe AR often complain of an uncomfortable awareness of the heartbeat, especially on lying down, and disagreeable thoracic pain caused by pounding of the heart against the chest wall. Tachycardia, occurring with emotional stress or exertion, may cause troubling palpitations and head pounding. Premature ventricular contractions are particularly distressing because of the great heave of the volume-loaded left ventricle during the postextrasystolic beat. These complaints may be present for many years before symptoms of overt LV dysfunction develop.

Physical Examination. In patients with chronic, severe AR, the head may bob with each heartbeat (de Musset sign), and water hammer pulses, with abrupt distention and quick collapse (Corrigan pulse), are evident. The arterial pulse often is prominent and can be best appreciated by palpation of the radial artery with the patient's arm elevated (see Chapter 11). A bisferiens pulse may be present and is more readily recognized in the brachial and femoral arteries than in the carotid arteries. A variety of auscultatory findings provide confirmation of a wide pulse pressure. The Traube sign (also known as pistol shot sounds) refers to booming systolic and diastolic sounds heard over the femoral artery, the Müller sign consists of systolic pulsations of the uvula, and the Duroziez sign consists of a systolic murmur heard over the femoral artery when it is compressed proximally and a diastolic murmur when it is compressed distally. Capillary pulsations (the Quincke sign) can be detected by transmitting a light through the patient's fingertips or exerting gentle pressure on the tip of a fingernail.

Systolic arterial pressure is elevated, and diastolic pressure is abnormally low. Korotkoff sounds often persist to zero even though the intra-arterial pressure rarely falls below 30 mm Hg. The point of change in Korotkoff sounds (i.e., the muffling of these sounds in phase

IV) correlates with the diastolic pressure. As heart failure develops, peripheral vasoconstriction may occur and arterial diastolic pressure may rise, even though severe AR is present. The Hill sign (an exaggerated difference in systolic blood pressure between the upper and lower extremities) is an artifact of sphygmomanometric measurements and is no longer considered a sign of severe AR.

The apical impulse is diffuse and hyperdynamic and is displaced laterally and inferiorly; systolic retraction may be detected over the parasternal region. A rapid ventricular filling wave often is palpable at the apex. The augmented stroke volume may create a systolic thrill at the base of the heart or suprasternal notch, and over the carotid arteries. In many patients, a carotid shudder is palpable.

Auscultation. The aortic regurgitant murmur, the principal physical finding in AR, is of high frequency and begins immediately after A₂. It may be distinguished from the murmur of pulmonic regurgitation by its earlier onset (i.e., immediately after A₂ rather than after P₂) and usually by the presence of a widened pulse pressure. The murmur is heard best with the diaphragm of the stethoscope while the patient is sitting up and leaning forward, with the breath held in deep exhalation. In severe AR, the murmur reaches an early peak and then shows a dominant decrescendo pattern throughout diastole.

The severity of AR correlates better with the duration than with the intensity of the murmur.²³ In mild AR, the murmur may be limited to early diastole and typically is high-pitched and blowing. In severe AR, the murmur is holodiastolic and may have a rough quality. When the murmur is musical (cooing dove murmur), it usually signifies eversion or perforation of an aortic cusp. In patients with severe AR and LV decompensation, equilibration of aortic and LV pressures in late diastole abolishes the late diastolic component of the regurgitant murmur. When AR is caused by primary valvular disease, the diastolic murmur is heard best along the left sternal border in the third and fourth intercostal spaces. However, when it is caused mainly by dilation of the ascending aorta, the murmur often is more readily audible along the right sternal border.

Many patients with chronic AR have a harsh systolic outflow murmur caused by the increased total LV stroke volume and ejection rate, which often radiates to the carotid vessels. The systolic murmur often is more readily audible than the diastolic murmur. It may be

TABLE 63-6 Stages of Chronic Aortic Regurgitation

STAGE	DEFINITION	VALVE ANATOMY	VALVE HEMODYNAMICS	HEMODYNAMIC CONSEQUENCES	SYMPTOMS
A	At risk of AR	Bicuspid aortic valve (or other congenital valve anomaly) Aortic valve sclerosis Diseases of the aortic sinuses or ascending aorta History of rheumatic fever or known rheumatic heart disease IE	AR severity none or trace	None	None
B	Progressive AR	Mild to moderate calcification of a trileaflet valve bicuspid aortic valve (or other congenital valve anomaly) Dilated aortic sinuses Rheumatic valve changes Previous IE	Mild AR: Jet width <25% of LVOT vena contracta <0.3 cm RVol <30 mL/beat RF <30% ERO <0.10 cm ² Angiography grade 1+ Moderate AR: Jet width 25%-64% of LVOT Vena contracta 0.3-0.6 cm RVol 30-59 mL/beat RF 30%-49% ERO 0.10-0.29 cm ² Angiography grade 2+	Normal LV systolic function Normal LV volume or mild LV dilation	None
C	Asymptomatic severe AR	Calcific aortic valve disease Bicuspid valve (or other congenital abnormality) Dilated aortic sinuses or ascending aorta Rheumatic valve changes IE with abnormal leaflet closure or perforation	Severe AR: Jet width ≥65% of LVOT Vena contracta >0.6 cm Holodiastolic flow reversal in the proximal abdominal aorta RVol ≥60 mL/beat RF ≥50% ERO ≥0.3 cm ² Angiography grade 3+ to 4+ In addition, diagnosis of chronic severe AR requires evidence of LV dilation	C1: Normal LVEF (≥50%) and mild-to-moderate LV dilation (LVESD ≤50 mm) C2: Abnormal LV systolic function with depressed LVEF (<50%) or severe LV dilation (LVESD >50 mm or indexed LVESD >25 mm/m ²)	None; exercise testing is reasonable to confirm symptom status
D	Symptomatic severe AR	Calcific valve disease Bicuspid valve (or other congenital abnormality) Dilated aortic sinuses or ascending aorta Rheumatic valve changes Previous IE with abnormal leaflet closure or perforation	Severe AR: Doppler jet width ≥65% of LVOT Vena contracta >0.6 cm Holodiastolic flow reversal in the proximal abdominal aorta RVol ≥60 mL/beat RF ≥50% ERO ≥0.3 cm ² Angiography grade 3+ to 4+ In addition, diagnosis of chronic severe AR requires evidence of LV dilation	Symptomatic severe AR may occur with normal systolic function (LVEF ≥50%), mild-to-moderate LV dysfunction (LVEF 40% to 50%), or severe LV dysfunction (LVEF <40%) Moderate-to-severe LV dilation is present	Exertional dyspnea or angina, or more severe HF symptoms

ERO = effective regurgitant orifice; HF = heart failure; IE = infective endocarditis; LVEF = left ventricular ejection fraction; LVESD = left ventricular end-systolic dimension; LVOT = left ventricular outflow tract; RF = regurgitant fraction; RVol = regurgitant volume.

From Nishimura RA, Otto CM, Bonow RO, et al: 2014 AHA/ACC guideline for the management of patients with valvular heart disease: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 63:e57, 2014.

higher-pitched and less rasping than the murmur of AS but often is accompanied by a systolic thrill. Palpation of the carotid pulses will elucidate the cause of the systolic murmur and differentiate it from the murmur of AS.

A₂ may be normal or accentuated when AR is caused by disease of the aortic root but is soft or absent when AR is caused by primary valve pathology. P₂ may be obscured by the early diastolic murmur. Thus S₂ may be absent or single or exhibit narrow or paradoxical splitting. A systolic ejection sound, presumably related to abrupt distention of the aorta by the augmented stroke volume, frequently is audible. A third heart sound (S₃) correlates with an increased LV end-diastolic volume. Its development may be a sign of impaired LV function, which is useful in identifying patients with severe AR who are candidates for surgical treatment.

A mid-diastolic and late diastolic apical rumble, the *Austin Flint murmur*, is common in severe AR and may occur in the presence of a

normal mitral valve. This murmur appears to be created by severe aortic reflux impinging on the anterior leaflet of the mitral valve or the free LV wall; convincing evidence for obstruction to mitral inflow in these patients is lacking.

Echocardiography

Echocardiography (see Chapter 14) is helpful in identifying the cause of AR (Fig. 63-13) and may demonstrate a bicuspid valve, thickening of the valve cusps, other congenital abnormalities, prolapse of the valve, a flail leaflet, or vegetation. In addition to leaflet anatomy and motion, the size and shape of the aortic root can be evaluated, although visualization of the ascending aorta is not always adequate, necessitating additional imaging procedures in some cases. Transthoracic imaging usually is satisfactory, but

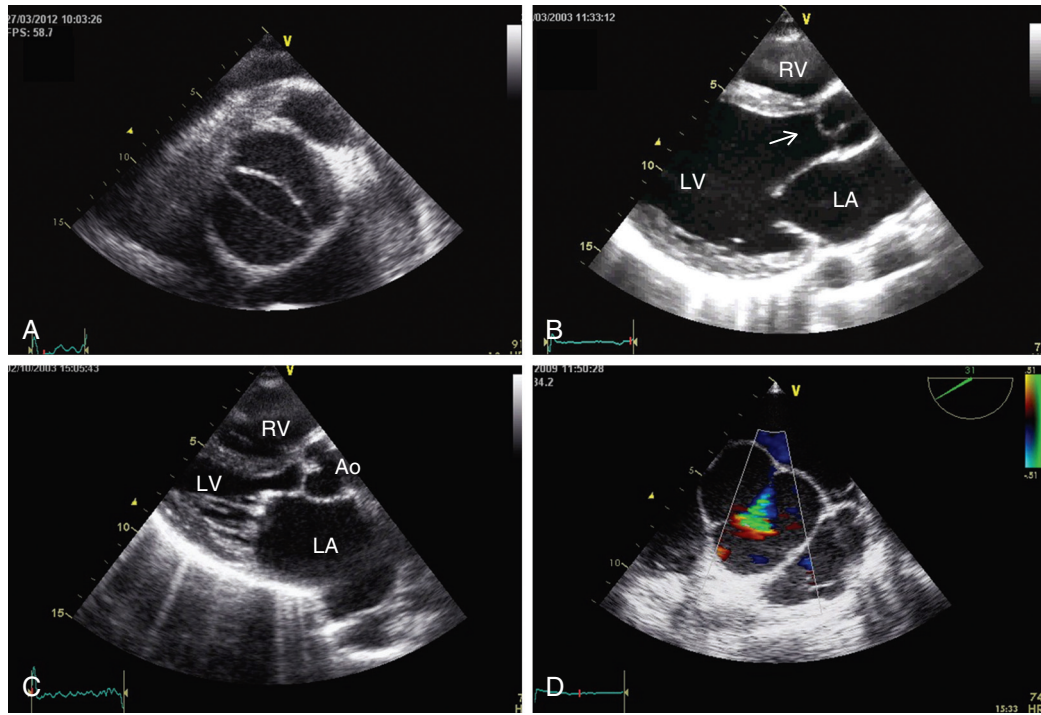

FIGURE 63-13 Role of echocardiography in the etiologic investigation of AR. **A**, Transthoracic parasternal short axis view showing a bicuspid aortic valve. **B**, Myxomatous aortic valve with a prolapse of the right coronary cusp (arrow). **C**, Rheumatic valvular disease with mitral and aortic involvement. **D**, TEE image showing a central regurgitant orifice secondary to annuloaortic ectasia. Ao = aorta; LA = left atrium; LV = left ventricle; RV = right ventricle. (From Tornos P, Evangelista A, Bonow RO: Aortic regurgitation. In Otto CM, Bonow RO [eds]: *Valvular Heart Disease: A Companion to Braunwald's Heart Disease*. 4th ed. Philadelphia, Saunders, 2013, pp 163-178.)

transesophageal echocardiography (TEE) often provides more detail, particularly of the aortic root.

Transthoracic echocardiography (TTE) is useful for the measurement of LV end-diastolic and end-systolic dimensions and volumes, ejection fraction, and mass (Videos 63-2A and 63-2B).^{38,118} Two-dimensional guided M-mode measurements of LV dimensions are recommended when possible, because the high temporal resolution of this modality allows more accurate identification of endocardial borders. Care is needed to ensure that measurements are not oblique and are at the same site on subsequent studies. When the M-line is oblique, two-dimensional measurements are made in conjunction with the calculation of biplane ventricular end-diastolic and end-systolic volumes. Recent studies have suggested that end-systolic volume is a strong predictor of adverse clinical outcomes.^{121,122-124} These measurements, when made serially, are of great value in selecting the optimal time for surgical intervention.

High-frequency fluttering of the anterior leaflet of the mitral valve during diastole may be seen in acute and chronic AR. However, it does not develop when the mitral valve is rigid, as occurs with rheumatic involvement. This sign, unlike the Austin Flint murmur, is present even in mild AR and results from the movement imparted to the anterior leaflet of the mitral valve by the jet of blood regurgitating from the aorta.

Doppler echocardiography and color flow Doppler imaging are the most sensitive and accurate noninvasive techniques for the diagnosis and evaluation of AR. They readily detect mild degrees of AR that may be inaudible on physical examination. Both the aortic regurgitant orifice size and aortic regurgitant flow can be estimated quantitatively (see Fig. 14-51) (Videos 63-3A and 63-3B),^{38,125} and such determinations are strongly recommended.¹ These quantitative data provide the basis for the definitions of mild, moderate, and severe AR (see Table 63-6) (Videos 63-4, 63-5A, 63-5B, 63-6A, and 63-6B). Serial studies permit determination of the progression of AR and its effect on the left ventricle.

Other Diagnostic Evaluation Modalities

Electrocardiography. The electrocardiogram (ECG) is not an accurate predictor of the severity of AR or cardiac weight. Chronic severe

AR results in left axis deviation and a pattern of LV diastolic volume overload, characterized by an increase in initial forces (prominent Q waves in leads I, aVL, and V₃ through V₆) and a relatively small wave in lead V₁. With the passage of time, these initial forces diminish, but the total QRS amplitude increases. The T waves may be tall and upright in the left precordial leads early in the course, but more commonly they are inverted, with ST-segment depression. An LV strain pattern correlates with the presence of dilation and hypertrophy (see Chapter 12). Intraventricular conduction defects occur late in the course and are usually associated with LV dysfunction. When AR is caused by an inflammatory process, prolongation of the PR interval may be present.

Radiography. Cardiac size is a function of the duration and severity of regurgitation and the state of LV function (see Fig. 15-12). In acute AR, cardiac enlargement may be minimal, but marked enlargement is a common finding in chronic AR. Typically, the left ventricle enlarges in an inferior and leftward direction, causing a significant increase in the long axis but sometimes causing little or no increase in the transverse diameter of the heart. Calcification of the aortic valve is uncommon in patients with isolated AR but is often present in patients with combined AS and AR. Distinct left atrial enlargement in the absence of heart failure suggests associated mitral valve disease. Aneurysmal dilation of the aorta suggests that aortic root disease (e.g., Marfan syndrome, cystic medial necrosis, annuloaortic ectasia) is responsible for the AR. Linear calcifications in the wall of the ascending aorta are seen in syphilitic aortitis but are nonspecific and also are observed in degenerative disease.

Angiography. For angiographic assessment of AR, contrast material should be injected rapidly (i.e., at 25 to 35 mL/sec) into the aortic root, and filming should be carried out in the right and left anterior oblique projections (see Chapter 19). Opacification may be improved by filming during a Valsalva maneuver. In acute AR, only a slight increase in LV end-diastolic volume is evident, but with the passage of time, both the end-diastolic volume and thickness of the LV wall increase, usually in parallel.¹¹⁹

Cardiac Magnetic Resonance. CMR provides accurate measurements of regurgitant volumes and the regurgitant orifice in AR (Fig. 63-14). It is the most accurate noninvasive technique for assessing LV end-systolic volume, diastolic volume, and mass (see Chapter 17). CMR accurately quantifies the severity of AR on the basis of the antegrade and retrograde flow volumes in the ascending aorta and is recommended when echocardiographic evaluation of regurgitation is suboptimal.^{45,126,127}

Disease Course: Natural History of Chronic Aortic Regurgitation

Moderately severe or even severe chronic AR often is associated with a generally favorable prognosis for many years. Quantitative measures of AR severity predict clinical outcome, and LV size and systolic function also are strong predictors of clinical outcome. In a study of 251 asymptomatic patients (mean age, 61 years), the 10-year survival was $94\% \pm 4\%$ in those with mild AR, compared with $69\% \pm 9\%$ in those with severe AR (Fig. 63-15).¹²³ By contrast, in series involving younger asymptomatic patients (mean age, 39 years) with severe AR and normal LV ejection fractions, the mortality rate was less than 1%/year,^{1,121} and more than 45% of the patients remained asymptomatic with normal LV function at 10 years. The average rate of developing symptoms or LV systolic dysfunction in these latter series was less than 6%/year (Fig. 63-16; see also Table e63-3).

As is the case for AS, however, once the patient becomes symptomatic, the downhill course becomes rapidly progressive. Congestive heart failure, punctuated by episodes of acute pulmonary edema, and sudden death may occur, usually in previously symptomatic patients who have considerable LV dilation. Data compiled in the presurgical era indicated that without surgical treatment, death usually occurred within 4 years after the development of angina pectoris and within 2 years after the onset of heart failure. Even in the current era, 4-year survival without surgery in patients with NYHA class III or IV symptoms is only approximately 30% (see Fig. e63-1).

Gradual deterioration of LV function may occur even during the asymptomatic period, and some patients may incur significant impairment of systolic function before the onset of symptoms (see Table 63-6). Numerous surgical series over the past two decades have indicated that depressed LV ejection fraction is among the most important determinants of mortality after AVR, particularly when LV

FIGURE 63-15 Composite endpoint of survival free of surgery for AR after diagnosis in asymptomatic patients. Patients are stratified according to quantitative criteria of the American Society of Echocardiography (QASE) for AR grading. The QASE-severe AR is defined as regurgitant volume (RV) greater than 60 mL/beat or effective regurgitant orifice (ERO) greater than 30 mm². The QASE-mild AR is defined as RV less than 30 mL/beat and ERO less than 10 mm², and QASE-moderate AR as greater than mild but not reaching QASE-severe criteria. The 5- and 10-year rates of the endpoint \pm standard error are indicated. Note the wide difference in outcomes according to QASE grading at baseline. (From Detaint D, Messika-Zeitoun D, Maalouf J, et al: Quantitative echocardiographic determinants of clinical outcome in asymptomatic patients with aortic regurgitation: A prospective study. *J Am Coll Cardiol Img* 1:1, 2008.)

FIGURE e63-1 Survival without surgery in 242 patients with chronic AR, demonstrating the importance of symptoms in determining outcome. Patients with NYHA class III or IV symptoms had a survival of only 28% at 4 years. By contrast, the 10-year survival in patients in class I was 75%, which was identical to that for an age-matched normal population. (From Dujardin KS, Enriquez-Sarano M, Schaff HV, et al: Mortality and morbidity of aortic regurgitation in clinical practice: A long-term follow-up study. *Circulation* 99:1851, 1999.)

dysfunction is irreversible and does not improve after operation.^{1,2,121} LV dysfunction is more likely to be reversible if detected early, before ejection fraction becomes severely depressed, before the left ventricle becomes markedly dilated, and before significant symptoms develop. It is therefore important to intervene surgically before these changes have become irreversible.¹¹⁸ Measures of LV systolic volume and systolic function are the most important predictors of clinical course in asymptomatic patients (see Table e63-3).^{23,121,122-124} Biomarkers such as BNP¹²⁴ and assessment of myocardial strain¹²⁸ also may play a role in the future in identifying high-risk patients, based on small series published to date, but more work is necessary before these additional measures are recommended for routine management.

Medical Management

General Principles for Asymptomatic Patients. Patients with mild or moderate AR who are asymptomatic with normal or only minimally increased cardiac size require no therapy but should be followed clinically and by echocardiography every 12 or 24 months. Asymptomatic patients with chronic severe AR and normal LV function should be examined at intervals of approximately 6 months. In addition to clinical examination, serial echocardiographic assessments of LV size and ejection fraction should be made. CMR usually is not necessary but may be useful in patients whose noninvasive test results are inconclusive or discordant with clinical findings or when further evaluation of aortic size is needed (see Fig. 63-14). Patients with mild to moderate AR and those with severe AR with a normal ejection fraction and only mild ventricular dilation may engage in aerobic forms of exercise. However, patients with AR who have limitations of cardiac reserve and/or evidence of declining LV function should not engage in vigorous sports or activities entailing heavy exertion. Systemic arterial diastolic hypertension, if present, should be treated because it increases the regurgitant flow; vasodilating agents such as nifedipine or ACE inhibitors are preferred, and beta-adrenergic blocking agents should be used with caution. AF and bradyarrhythmias are poorly tolerated and should be prevented, if possible. If these arrhythmias occur, they must be treated promptly and vigorously. Most patients with AR do not need prophylaxis for infective endocarditis (see Chapter 64).

FIGURE 63-16 Three series examining the natural history of chronic asymptomatic AR in patients with normal LV ejection fraction at rest, each comprising more than 100 patients. At 10 years, 54% to 70% of patients remained asymptomatic with normal LV function, such that the risk of developing symptoms, LV dysfunction (LVD), or death is approximately 3% to 6%/year. The endpoints encountered in these series are indicated. Most patients who deteriorated developed symptoms leading to aortic valve replacement. However, 25% to 30% of the endpoints, either asymptomatic LVD (Asym LVD) or death, occurred without warning symptoms. (From Bonow RO: Chronic mitral regurgitation and aortic regurgitation: Have indications for surgery changed? *J Am Coll Cardiol* 61:693, 2013. Data modified from Bonow RO, Lakatos E, Maron BJ, et al: Serial long-term assessment of the natural history of asymptomatic patients with chronic aortic regurgitation and normal left ventricular systolic function. *Circulation* 84:1625, 1991; Tornos MP, Olona M, Permanyer-Miralda G, et al: Clinical outcome of severe asymptomatic chronic aortic regurgitation: A long term prospective follow up study. *Am Heart J* 130:333, 1995; and Borer JS, Hochreiter C, Herrold EM, et al: Prediction of indications for valve replacement among asymptomatic and minimally symptomatic patients with chronic aortic regurgitation and normal left ventricular performance. *Circulation* 97:525, 1998.)

Drug Treatment. No specific therapy to prevent disease progression in chronic AR is currently available. Uncertainty remains about whether patients with chronic AR and evidence of significant volume overload (increased end-diastolic dimension or volume) should be considered for vasodilator therapy to alter the natural history of chronic LV volume overload.¹²⁹ Short-term studies spanning 6 months to 2 years have demonstrated beneficial hemodynamic effects of oral hydralazine, nifedipine, felodipine, and ACE inhibitors. One randomized study followed asymptomatic patients with severe AR for 6 years, comparing the effects of long-acting nifedipine (in 69 patients) and digoxin (in 74 patients) on LV function and symptoms. Nifedipine delayed the need for operation: At 6 years, 85% of patients receiving nifedipine remained asymptomatic, with a normal LV ejection fraction, compared with only 65% of patients receiving digoxin. However, a second randomized trial compared placebo, long-acting nifedipine, and enalapril in 95 consecutive patients over a period of 7 years. Neither nifedipine nor enalapril reduced the development of symptoms or LV dysfunction warranting AVR compared with placebo. Moreover, neither drug significantly altered LV dimension, ejection fraction, or mass over time compared with placebo. In view of this equipoise, definitive recommendations regarding the indications for long-acting nifedipine or ACE inhibitors are not possible.^{1,118}

It is conceivable that blockade of the renin-angiotensin system may provide additional myocardial benefits beyond peripheral vasodilation by direct mechanisms to reduce interstitial fibrosis and remodeling. Such promising effects have been demonstrated in animal models¹³⁰ but are yet to be tested in prospective clinical trials. A retrospective Scottish registry study of 2266 patients with at least moderate AR reported a 44% reduction in all-cause mortality (HR, 0.56 [95% CI, 0.64 to 0.89]; $P < 0.01$) over a mean 4.4-year period in the 876 patients taking ACE inhibitors or angiotensin receptor blockers (ARBs) compared with the 1390 patients who did not receive these drugs.¹³¹ Patients taking ACE inhibitors/ARBs were younger, however, with significantly greater use of other drugs (including aspirin, statins, beta blockers, and calcium channel blockers) that might affect outcome, because most events were considered cardiovascular and not directly related to AR. Nevertheless, ACE inhibitor/ARB therapy was associated with a 32% reduction in AR events (AVR, heart failure hospitalization and heart failure death) ($P < 0.01$). Another retrospective study reported beneficial effects of beta blocker therapy on survival in patients with AR.¹³² However, patients receiving beta blockers were younger than those not taking beta blockers and also demonstrated a greater frequency of concomitant therapy with ACE inhibitors, statins, aspirin, and calcium channel blockers that might have influenced outcome. More than two thirds of patients in this study had heart failure and 25% had AF, so extrapolation to asymptomatic patients is difficult. Moreover, interpretation of the survival results is complicated by greater intervention with AVR and CABG in those taking beta blockers. Thus these studies are not definitive and indicate the need for prospectively designed trials before ACE inhibitor or beta blocker therapy could be considered in asymptomatic patients with chronic AR.

Symptomatic Patients. AVR is the treatment of choice for symptomatic patients. Chronic medical therapy may be necessary for some patients who refuse surgery or are considered to be inoperable because of comorbid conditions. These patients should receive an aggressive heart failure regimen (see Chapter 25) with ACE inhibitors (and perhaps other vasodilators), digoxin, diuretics, and salt restriction; beta blockers may also be beneficial.¹³² Even though nitroglycerin and other nitrates are not as helpful in relieving anginal pain in patients with AR as they are in patients with coronary artery disease or AS, they are worth a try.

In patients who are candidates for surgery but who have severely decompensated LV dysfunction, vasodilator therapy may be particularly helpful in stabilizing patients while preparing for operation.

Surgical Treatment

INDICATIONS FOR OPERATION. A proposed management strategy for patients with chronic severe AR is shown in Figure 63-17. Because of their excellent prognosis in the short and medium term, operative correction should be deferred in patients with chronic severe AR who are asymptomatic, exhibit good exercise tolerance, and have an ejection fraction greater than 50% without severe LV dilation (i.e., end-systolic diameter 50 mm or less) or progressive LV dilation on serial echocardiograms. In the absence of obvious

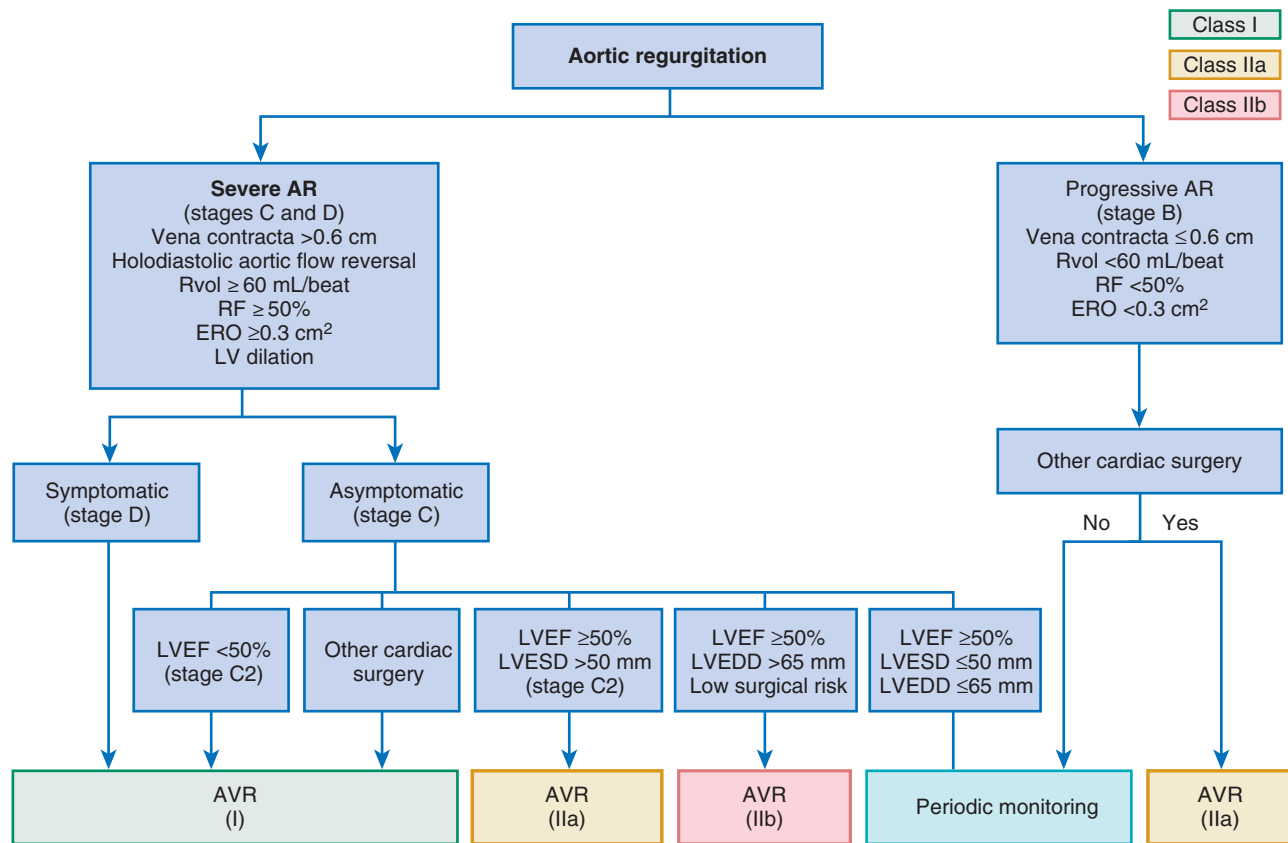

FIGURE 63-17 Management strategy for patients with chronic severe AR. AVR = aortic valve replacement (valve repair may be appropriate in selected patients); ERO = effective regurgitant orifice; LVEDD = left ventricular end-diastolic dimension; LVEF = left ventricular ejection fraction; LVESD = left ventricular end-systolic dimension; RF = regurgitant fraction; RVol = regurgitant volume. (From Nishimura RA, Otto CM, Bonow RO, et al: 2014 AHA/ACC guideline for the management of patients with valvular heart disease: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 63:e57: 2014.)

contraindications or serious comorbidity, surgical treatment is advisable for symptomatic patients with severe AR and for asymptomatic patients with either an ejection fraction of 50% or less or severe LV dilation (end-systolic diameter >50 mm).^{1,2} Between these two ends of the clinical-hemodynamic spectrum are many patients in whom it may be difficult to balance the immediate risks of operation and the continuing risks of an implanted prosthetic valve, on the one hand, against the hazards of allowing a severe volume overload to damage the left ventricle, on the other.^{118,121}

Because severe symptoms (NYHA class III or IV) and LV dysfunction with an ejection fraction less than 50% are independent risk factors for poor postoperative survival (Fig. 63-18), surgery should be carried out in patients with even mild symptoms (NYHA class II) before severe LV dysfunction has developed.^{1,2,118,121} Even after successful correction of AR, patients with severe LV dysfunction may have persistent cardiomegaly and depressed LV function. Such patients often exhibit persistent histologic changes in the left ventricle, including massive fiber hypertrophy and increased interstitial fibrous tissue. Therefore it is highly desirable to operate on patients before irreversible LV changes have occurred.

Because AR has complex effects on preload and afterload, the selection of appropriate indices of ventricular contractility to identify patients for operation is challenging. The relationship between end-systolic wall stress and ejection fraction or percentage fractional shortening is a useful measurement,³⁵ as are more load-independent measures of LV contractility. However, in the absence of such complex measurements, serial changes in ventricular end-diastolic and end-systolic volumes or dimensions can be used to detect the relative deterioration of ventricular function.¹¹⁸ Although LV end-diastolic and end-systolic volumes and ejection phase indices (e.g., ejection fraction, ventricular fraction shortening) are strongly influenced by

loading conditions, they are nonetheless useful empirical predictors of postoperative function.

Serial echocardiograms should be obtained to detect changes in LV size and function in asymptomatic patients with severe AR (see Fig. 63-17). Impaired LV function at rest is the basis for selecting patients for operation; normal LV function at rest with failure of the ejection fraction to rise normally with exercise is not considered an indication for surgery per se, but is an early warning sign that portends impaired function at rest. Echocardiographic measurements of LV size also are important, with M-mode LV end-diastolic and end-systolic dimensions, when possible, and with biplane apical calculations of the end-systolic volume index. Echocardiographic measurements should be made with side-by-side comparison of previous serial studies. A consistent change in dimensions or volumes, greater than measurement variability, must be ensured before recommending AVR for asymptomatic patients on the basis of these numbers alone.

Asymptomatic patients with severe AR but normal LV function have an excellent prognosis and do not require prophylactic operation (see Table e63-3). On average, less than 6% of patients/year require operation because of the development of symptoms or of LV dysfunction (see Fig. 63-16), although the rate of symptom development is higher in patients older than 60 years.¹²³ The LV end-systolic dimension determined by echocardiography is valuable in predicting outcome in asymptomatic patients. Patients with severe AR and an end-systolic diameter less than 40 mm almost invariably remain stable and can be followed without immediate surgery. However, patients with an end-systolic diameter of more than 50 mm have a 19% likelihood/year of developing symptoms of LV dysfunction, and those with an end-systolic diameter more than 55 mm are at increased risk for development of irreversible LV dysfunction if they are not operated on. Postoperative function and survival in this latter group

FIGURE 63-18 Long-term postoperative survival in patients with AR, stratified according to the severity of preoperative symptoms and preoperative LV ejection fraction (LVEF). Patients with NYHA class III or IV symptoms experienced significantly worse survival than those with class I or II symptoms whether the echocardiographic LVEF was higher than 0.50 (**A**) or less than 0.50 (**B**) without associated coronary artery disease. (From Klodas E, Enriquez-Sarano M, Tajik AJ, et al: *Optimizing timing of surgical correction in patients with severe aortic regurgitation: Role of symptoms*. *J Am Coll Cardiol* 30:746, 1997.)

are determined by the severity of symptoms and degree and duration of LV dysfunction.^{118,121} Indexed end-systolic dimension or volume (ESVI) may be a more robust indicator for timing of surgical intervention.^{122,123} Patients with an ESVI of 45 mL/m² or greater are at higher risk for adverse outcomes.¹²³ Further data on the use of ESVI are needed before this approach becomes standard.

In summary, the following considerations apply to the selection of patients with chronic AR for surgical treatment.^{1,2} Operation should be deferred in asymptomatic patients with normal and stable LV function and should be recommended for symptomatic patients (see Fig. 63-17). In asymptomatic patients with LV dysfunction, a decision should be based not on a single abnormal measurement but rather on several observations of depressed performance and impaired exercise tolerance, carried out at intervals of 2 to 4 months. If evidence of LV dysfunction is borderline or inconsistent, continued close follow-up is indicated. If abnormalities are progressive and consistent (i.e., LV ejection fraction <50% or LV end-systolic diameter rises to >50 mm), operation should be strongly considered, even in asymptomatic patients. Symptomatic patients with severe AR who have normal, mildly depressed, or moderately depressed LV function

should undergo AVR. Patients with severely impaired LV function (ejection fraction <25%) are at high surgical risk and have a guarded prognosis, even after successful AVR. However, their outlook is also extremely poor when they receive medical therapy alone, and their management should be considered on an individual basis.

The indications for surgery for patients with severe AR secondary to aortic sinus or ascending aortic disease are similar to those for patients with primary valvular disease. However, progressive expansion of the aortic sinuses and/or ascending aorta to a diameter greater than 55 mm with any degree of regurgitation in patients with a bicuspid valve (or other connective tissue disorder) also is an indication for repair of the aortic sinuses or replacement of the ascending aorta.¹ This threshold is decreased to 50 mm in patients with risk factors for dissection (family history of aortic dissection or rate of increase in diameter of ≥0.5 cm/year).^{1,133} In addition, in patients with indications for AVR as noted previously, concomitant surgery on the aortic sinuses or ascending aorta is indicated if the amount of aortic dilation is greater than 45 mm.^{1,133}

As is the case for patients with other valvular lesions, adult surgical candidates who may have underlying coronary artery disease, based on symptoms, age, sex, and risk factors, should undergo preoperative coronary arteriography. Those with coronary artery stenoses should undergo revascularization at the time of AVR.

OPERATIVE PROCEDURES. The standard surgical approach for chronic AR is AVR. Concurrent aortic root replacement is performed when aortic dilation is the cause of or accompanies valve dysfunction. However, experience is accumulating with surgical aortic valve repair, which is a viable option for selected patients in experienced centers.¹³⁴⁻¹³⁸ Occasionally, when a leaflet has been torn from its attachments to the aortic annulus by trauma, surgical repair may be possible, and in patients with AR secondary to prolapse of an aortic leaflet, aortic cusp resuspension or cusp resection may be used. When AR is caused by leaflet perforation resulting from healed infective endocarditis, a pericardial patch can be used for repair. However, unlike patients with chronic MR, the large majority of patients with pure AR will require AVR rather than repair. Transcatheter AVR for AR is under investigation but is not an established approach.¹³⁹

Because an increasing proportion of patients with severe isolated AR coming to operation now have primary aortic root rather than primary valvular disease, an increasing number can be treated surgically by correcting the dilated aortic root.^{136,137} Aneurysmal dilation of the ascending aorta requires excision, replacement with a graft that includes a prosthetic valve, and reimplantation of the coronary arteries. In some patients with aortic root disease, the native valve can be spared when the aortic root is replaced or repaired (Fig. 63-19).

When AVR is performed in patients with severe AR, the aortic annulus often is larger than in patients with AS. Hence a larger prosthetic valve can be inserted, and mild postoperative obstruction to LV outflow is less of a problem than it is in some patients with AS. In general, the associated risks and results of AVR in patients with AR are similar to those in patients with AS, with a large proportion of patients exhibiting striking relief of symptoms. Reductions in heart size and in LV diastolic volume and mass occur in most patients and may be striking. Exceptions are seen in patients who are in NYHA class III or IV heart failure and/or patients who have severe LV dysfunction preoperatively. As is true for patients with AS, the operative risk of AVR for patients with AR depends on the general condition of the patient, state of LV function, and skill and experience of the surgical team. The mortality rate ranges from 3% to 8% in most medical centers (see Table 63-5). A late mortality of approximately 5% to 10%/year is observed in survivors who had marked cardiac enlargement and/or prolonged LV dysfunction preoperatively. Follow-up studies have shown both early rapid and then slower long-term reductions in LV mass, ejection fraction, myocyte hypertrophy, and ventricular fibrous content after surgical relief of AR. By extending the indications for operation to symptomatic patients with normal LV function, as well as to asymptomatic patients with LV dysfunction, early and late results are improving. With the continued improvement of

FIGURE 63-19 Repair of AR caused by aortic root dilation. **A**, Remodeling of the aortic root with replacement of all three aortic sinuses. **B**, Reimplantation of the aortic valve in patients with annuloaortic ectasia and aortic root aneurysm. **C, D**, Aortic annuloplasty in patients with annuloaortic ectasia. (From David TE: Aortic root aneurysms: Remodeling or composite replacement? *Ann Thorac Surg* 64:1564, 1997.)

surgical techniques and results, it probably will become possible to extend the recommendation for operative treatment to asymptomatic patients with severe AR, normal LV systolic function, and only mild LV dilation. However, in view of the risks of operation and the long-term complications of currently available prosthetic valves, we do not believe that the time for such a policy has yet arrived.

Acute Aortic Regurgitation

Acute AR is caused most commonly by infective endocarditis, aortic dissection, or trauma (see Chapters 57, 64, and 72).¹⁴⁰ The characteristic features of acute AR are tachycardia and an increase in LV diastolic pressures. In contrast with the pathophysiologic events in chronic AR just described, in which the left ventricle can adapt to the increased hemodynamic load, in acute AR the regurgitant volume fills a ventricle of normal size that cannot accommodate the combined large regurgitant volume and inflow from the left atrium. Because the ability of total stroke volume to rise acutely is limited, forward stroke volume declines. The sudden increase in LV filling causes the LV diastolic pressure to rise rapidly above left atrial pressure during early diastole (see Fig. 63-12), causing the mitral valve to close prematurely in diastole. Premature closure of the mitral valve, together with tachycardia that also shortens diastole, reduces the time interval during which the mitral valve is open. The tachycardia may compensate for the reduced forward stroke volume, and the LV and aortic systolic pressures may exhibit little change. However, acute severe AR may cause profound hypotension and cardiogenic shock. In light of the limited ability of the left ventricle to tolerate acute severe AR, patients with this valvular lesion often develop clinical manifestations of sudden cardiovascular collapse, including weakness, severe dyspnea, and profound hypotension secondary to the reduced stroke volume and elevated left atrial pressure. In some patients, the aortic diastolic pressure equilibrates with the elevated LV diastolic pressure.

Physical Examination. Patients with acute severe AR characteristically appear gravely ill, with tachycardia, severe peripheral vasoconstriction, and cyanosis, and sometimes pulmonary congestion and edema. The peripheral signs of AR are often not impressive and certainly not as dramatic as in patients with chronic AR. The normal or only slightly widened pulse pressure may lead to serious underestimation of the severity of the valvular lesion. The LV impulse is normal or almost normal, and the rocking motion of the chest characteristic of chronic AR is not apparent. S_1 may be soft or absent because of premature closure of the mitral valve, and the sound of mitral valve closure in mid- or late diastole occasionally is audible. Closure of the mitral valve may be incomplete, however, and diastolic MR may occur. Evidence of pulmonary hypertension, with an accentuated P_2 , S_3 , and S_4 , frequently is present.

The early diastolic murmur of acute AR is lower-pitched and of shorter duration compared with that of chronic AR, because as LV diastolic pressure rises, the (reverse) pressure gradient between the aorta and left ventricle is rapidly reduced. A systolic murmur is common, resulting in to-and-fro sounds. The Austin Flint murmur often is present but is of brief duration and ceases when LV pressure exceeds left atrial pressure in diastole. With premature diastolic closure of the mitral valve, the presystolic portion of the Austin Flint murmur is eliminated.

Echocardiography. In acute AR, the echocardiogram reveals a dense, diastolic Doppler signal with an end-diastolic velocity approaching zero and premature closure and delayed opening of the mitral valve. LV size and ejection fraction are normal. These findings contrast with those in chronic AR, in which end-diastolic dimensions and wall motion are increased. Occasionally, with equilibration of aortic and LV pressures in diastole, premature opening of the aortic valve may be detected.

Other Diagnostic Evaluation Modalities. **Electrocardiography.** In acute AR, the ECG may or may not show LV hypertrophy, depending on the severity and duration of the regurgitation. However, nonspecific ST-segment and T wave changes are common.

Radiography. In acute AR, radiographic examination often reveals evidence of marked pulmonary venous hypertension and pulmonary edema. The cardiac silhouette usually is remarkably normal, although left atrial enlargement may be present, and depending on the cause of the AR, enlargement of the ascending aorta may be seen.

Management of Acute Aortic Regurgitation. Because early death caused by LV failure is frequent in patients with acute severe AR despite intensive medical management, prompt surgical intervention is indicated. Even a normal ventricle cannot sustain the burden of acute, severe volume overload. Therefore the risk of acute AR is much greater than that of chronic AR. While the patient is being prepared for surgery, treatment with an intravenous positive inotropic agent (dopamine or dobutamine) and/or a vasodilator (nitroprusside) often is necessary. The agent and dosage should be selected on the basis of arterial pressure (see Chapter 24). Beta blockers and intra-aortic balloon counterpulsation are contraindicated, because either lowering the heart rate or augmenting peripheral resistance during diastole can lead to rapid hemodynamic decompensation. In hemodynamically stable patients with acute AR secondary to active infective endocarditis, operation may be deferred to allow 5 to 7 days of intensive antibiotic therapy (see Chapter 64). However, AVR should be undertaken at the earliest sign of hemodynamic instability or if echocardiographic evidence of diastolic closure of the mitral valve develops.

Bicuspid Aortic Valve Disease

Epidemiology

A congenital bicuspid aortic valve is present in approximately 1% to 2% of the population and is more prevalent in men, accounting for 70% to 80% of cases. In a subset of patients with bicuspid aortic valve, familial clustering consistent with an autosomal dominant inheritance with incomplete penetrance has been documented.⁴ In some families with bicuspid aortic valve and associated congenital anomalies, a mutation in the *NOTCH1* gene has been described.

Pathophysiology

The most prevalent anatomy for a bicuspid valve is two cusps with a right-left systolic opening, consistent with congenital fusion of the right and left coronary cusps, seen in 70% to 80% of patients (Videos 63-7A, 63-7B, and 63-7C). An anterior-posterior orientation, with fusion of the right and noncoronary cusps, is less common, seen in approximately 20% to 30% of cases.^{141,142} Fusion of the left and noncoronary cusps is rarely seen. A prominent ridge of tissue or raphe may be present in the larger of the two cusps so that the closed valve in diastole may mimic a trileaflet valve. Echocardiographic diagnosis relies on imaging the systolic leaflet opening with only two aortic commissures (Videos 63-8A and 63-8B). Unicuspid valves are distinguished from a bicuspid valve by having only one aortic commissure.

Bicuspid aortic valve disease is associated with an aortopathy, with dilation of the ascending aorta related to accelerated degeneration of the aortic media (see Chapter 57).^{4,141} The presence, location, and severity of aortic dilation is related to valve morphology but does not appear to be related to the severity of valve dysfunction per se.¹⁴³ The risk of aortic dissection in patients with a bicuspid aortic valve is five to nine times higher than the general population.^{4,144} Some studies have also suggested an association between bicuspid aortic valve disease (anterior-posterior leaflet opening) and mitral valve prolapse (MVP).¹⁴⁵

Clinical Presentation

Patients with a bicuspid valve may be diagnosed at any age on the basis of the presence of an aortic ejection sound or a systolic or diastolic murmur. Some patients, however, initially are diagnosed on echocardiography requested for other reasons, and others are diagnosed through a family history of bicuspid aortic valve disease.¹⁴⁶ Often, the diagnosis is unknown until the physical examination reveals manifestations of valve dysfunction or the patient develops symptoms.

Disease Course

Most bicuspid valves function normally until late in life, although a subset of patients present in childhood or adolescence with valve dysfunction. Overall, survival is not different from population estimates.^{147,148} Risk factors for cardiac events are age older than 30 years, moderate or severe AR, and moderate or severe AS. Over a mean follow-up period of 9 years, primary cardiac events occurred in 25% of 642 ambulatory adults with a bicuspid valve. Events included aortic valve or root replacement (22%), hospitalization for heart failure (2%), and cardiac death (3%) (Fig. 63-20). Over their lifetime, approximately 20% of patients with bicuspid valves develop severe AR requiring AVR between the ages of 10 and 40 years. Patients with a bicuspid aortic valve also are at increased risk for endocarditis (0.4/100,000), accounting for approximately 1200 deaths/year in the United States. However, most patients with a bicuspid valve develop calcific valve stenosis later in life, typically presenting with severe AS after the age of 50 years. Although the histopathologic features of calcific stenosis of a bicuspid aortic valve are no different from those of a trileaflet valve, the turbulent flow and increased leaflet stress caused by the abnormal architecture are postulated to result in accelerated valve changes, providing an explanation for the earlier average age at presentation in patients with a bicuspid, compared with trileaflet, stenotic valve. Bicuspid valve disease accounts for greater than 50% of AVRs in the United States³ and is a common cause of calcific AS, even in older persons.

FIGURE 63-20 Outcome of patients with bicuspid aortic valves. The frequency of primary cardiac events in patients with more than one risk factor at baseline ($n = 142$) was 65% (standard deviation [SD] = 5%); in all participants ($N = 642$), 25% (SD = 2%); in patients with one risk factor at baseline ($n = 306$), 18% (SD = 3%); and in patients with no risk factors at baseline ($n = 194$), 6% (SD = 2%). The risk factors for primary cardiac events were age older than 30 years, moderate or severe AR, and moderate or severe AS. (From Tzemos N, Therrien J, Yip J, et al: Outcomes in adults with bicuspid aortic valves. *JAMA* 300:1317, 2008.)

The aortopathy associated with bicuspid valve disease often results in aortic dilation and carries an increased risk of aortic dissection. The magnitude of risk appears to vary depending on valve and aortic morphology and on a family history of aortic involvement.¹⁴⁹⁻¹⁵¹

Management

The management of bicuspid aortic valve disease is directed toward the hemodynamic consequences of valve dysfunction—AS or AR—as discussed in these sections earlier. Currently, there are no effective medical therapies to prevent progressive valve deterioration when a bicuspid valve is diagnosed. In addition to appropriate follow-up for valve dysfunction, evaluation of the ascending aorta is needed, often with CT or CMR to ensure adequate visualization and accurate measurement of the aortic sinuses and ascending aorta (see Fig. 63-14).¹⁵² If AVR is needed for stenosis or regurgitation, concurrent aortic root replacement is recommended if the maximum aortic dimension (measured at end-diastole) exceeds 45 mm.^{1,153} Even in the absence of aortic valve disease, aortic root replacement is recommended when the aortic dimension exceeds 55 mm in adults with a bicuspid aortic valve and may be considered with an aortic diameter of 50 mm if there is a positive family history or evidence of rapid progression.^{1,133}

MITRAL VALVE DISEASE

Mitral Stenosis

Causes and Pathology

The predominant cause of MS is rheumatic fever,¹⁵⁴ with rheumatic changes present in 99% of stenotic mitral valves excised at the time of mitral valve replacement. Approximately 25% of all patients with rheumatic heart disease have isolated MS, and approximately 40% have combined MS and MR. Multivalve involvement is seen in 38% of patients with MS, with the aortic valve affected in approximately 35% and the tricuspid valve in approximately 6%. The pulmonic valve is rarely affected. Two thirds of all patients with rheumatic MS are

female. The interval between the initial episode of rheumatic fever (see Chapter 83) and clinical evidence of mitral valve obstruction is variable, ranging from a few years to more than 20 years.¹⁵⁵

Rheumatic fever results in characteristic changes of the mitral valve; diagnostic features are thickening at the leaflet edges, fusion of the commissures, and chordal shortening and fusion¹⁵⁶ (Fig. 63-21). With acute rheumatic fever, the changes include inflammation and edema of the leaflets, with small fibrin-platelet thrombi along the leaflet contact zones. Subsequent scarring leads to the characteristic valve deformity, with obliteration of the normal leaflet architecture by fibrosis, neovascularization and increased collagen and tissue cellularity. Aschoff bodies, the pathologic hallmark of rheumatic disease, are seen most frequently in the myocardium, not the valve tissue, with Aschoff bodies identified in only 2% of autopsied patients with chronic valve disease.

These anatomic changes lead to a typical functional appearance of the rheumatic mitral valve. In earlier stages of the disease, the relatively flexible leaflets snap open in diastole into a curved shape because of restriction of motion at the leaflet tips (see Fig. 14-37). This diastolic doming is most evident in the motion of the anterior leaflet and becomes less prominent as the leaflets become more fibrotic and calcified. The symmetrical fusion of the commissures results in a small central oval orifice in diastole that on pathologic specimens is shaped like a fish mouth or buttonhole because the anterior leaflet is not in the physiologic open position (see Fig. 63-21, right; see also Fig. 14-38). With end-stage disease, the thickened leaflets may be so adherent and rigid that they cannot open or shut, with consequent reduction in or, rarely, even abolition of the first heart sound, and leading to combined MS and MR. When rheumatic fever results exclusively or predominantly in contraction and fusion of the chordae tendineae, with little fusion of the valvular commissures, dominant MR results.

Debate continues about whether the anatomic changes of severe MS result from recurrent episodes of rheumatic fever or from a chronic autoimmune process caused by cross-reactivity between a streptococcal protein and valve tissue (see Chapter 83), or whether calcific valve disease is superimposed. Evidence supporting recurrent infection as an important factor in disease progression includes the correlation between the geographic variability in the prevalence of rheumatic heart disease and the age at which patients present with severe MS. In North America and Europe, where there is approximately 1 case/100,000 population, patients present with severe valve

obstruction in the sixth decade of life. By contrast, in Africa, with a disease prevalence of 35/100,000, severe disease often is seen in teenagers. Conversely, evidence favoring superimposed calcific valve disease is the observation that restenosis after mitral valvuloplasty is caused by leaflet thickening and fibrosis, rather than representing recurrent commissural fusion.¹⁵⁷

Congenital MS is uncommon and typically is diagnosed in infancy or early childhood (see Chapter 62). MS is a rare complication of malignant carcinoid disease, systemic lupus erythematosus, rheumatoid arthritis, and mucopolysaccharidoses of the Hunter-Hurler phenotype, Fabry disease, and Whipple disease. Methysergide therapy is an unusual but documented cause of MS. The association of atrial septal defect with rheumatic MS is called Lutembacher syndrome.

Other conditions may result in obstruction to LV inflow, including a left atrial tumor, particularly myxoma (see Chapter 85), ball valve thrombus in the left atrium (usually associated with MS), infective endocarditis with large vegetations (see Chapter 64), or a congenital membrane in the left atrium (i.e., cor triatriatum; see Chapter 62). In older patients, extensive mitral annular calcification may result in restriction of the size and motion of the annulus and may extend onto the base of the mitral leaflets, resulting in functional MS, although obstruction rarely is severe.^{158,159} Mitral annular calcification often develops in patients with calcific aortic valve disease.^{160,161}

Pathophysiology

The most useful descriptor of the severity of mitral valve obstruction is the degree of valve opening in diastole, or the mitral valve orifice area. In normal adults, the cross-sectional area of the mitral valve orifice is 4 to 6 cm² (Table 63-7). When the orifice is reduced to approximately 2 cm², which is considered to represent mild MS, blood can flow from the left atrium to the left ventricle only if propelled by a small, although abnormal, pressure gradient. When the mitral valve opening is reduced to 1 cm², which is considered to represent severe MS,¹⁶² a left atrioventricular pressure gradient of approximately 20 mm Hg (and therefore, in the presence of a normal LV diastolic pressure, a mean left atrial pressure >25 mm Hg) is required to maintain normal cardiac output at rest (Fig. 63-22; see also Fig. 19-14).

The transvalvular pressure gradient for any given valve area is a function of the square of the transvalvular flow rate.¹⁶² Thus a doubling of flow rate quadruples the pressure gradient. The elevated left atrial pressure, in turn, raises pulmonary venous and capillary pressures, resulting in exertional dyspnea. The first bouts of dyspnea in

TABLE 63-7 Stages of Mitral Stenosis

STAGE	DEFINITION	VALVE ANATOMY	VALVE HEMODYNAMICS	HEMODYNAMIC CONSEQUENCES	SYMPTOMS
A	At risk for MS	Mild valve doming during diastole	Normal transmitral flow velocity	None	None
B	Progressive MS	Rheumatic valve changes with commissural fusion and diastolic doming of the mitral valve leaflets Planimetered MVA $>1.5 \text{ cm}^2$	Increased transmitral flow velocities MVA $>1.5 \text{ cm}^2$ Diastolic pressure half-time $<150 \text{ msec}$	Mild to moderate LA enlargement Normal pulmonary pressure at rest	None
C	Asymptomatic severe MS	Rheumatic valve changes with commissural fusion and diastolic doming of the mitral valve leaflets Planimetered MVA $\leq 1.5 \text{ cm}^2$ (MVA $\leq 1 \text{ cm}^2$ with very severe MS)	MVA $\leq 1.5 \text{ cm}^2$ (MVA $\leq 1 \text{ cm}^2$ with very severe MS) Diastolic pressure half-time $\geq 150 \text{ msec}$ (Diastolic pressure half-time $\geq 220 \text{ msec}$ with very severe MS)	Severe LA enlargement Elevated PASP $>30 \text{ mm Hg}$	None
D	Symptomatic severe MS	Rheumatic valve changes with commissural fusion and diastolic doming of the mitral valve leaflets Planimetered MVA $\leq 1.5 \text{ cm}^2$	MVA $\leq 1.5 \text{ cm}^2$ (MVA $\leq 1 \text{ cm}^2$ with very severe MS) Diastolic pressure half-time $\geq 150 \text{ msec}$ (Diastolic pressure half-time $\geq 220 \text{ msec}$ with very severe MS)	Severe LA enlargement Elevated PASP $>30 \text{ mm Hg}$	Decreased exercise tolerance Exertional dyspnea

The transmitral mean pressure gradient should be obtained to determine the full hemodynamic effect of the MS and usually is >5 to 10 mm Hg in severe MS; however, because of the variability of the mean pressure gradient with heart rate and forward flow, it has not been included in the criteria for severity.

LA = left atrium; MVA = mitral valve area; PASP = pulmonary artery systolic pressure.

From Nishimura RA, Otto CM, Bonow RO, et al: 2014 AHA/ACC guideline for the management of patients with valvular heart disease: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 63:e57, 2014.

FIGURE 63-22 Schematic representation of LV, aortic, and left atrial (LA) pressures, showing normal (NL) relationships and alterations with mild and severe MS. Corresponding classic auscultatory signs of MS are shown at the bottom of the diagram. The higher left atrial v wave of severe MS causes earlier pressure crossover and earlier mitral valve (MV) opening, leading to a shorter time interval between aortic valve (AV) closure and the opening snap (OS). The higher left atrial end-diastolic pressure with severe MS also results in later closure of the mitral valve. With severe MS, the diastolic rumble becomes longer and there is accentuation of the pulmonic component (P_2) of the second heart sound (S_2) in relation to the aortic component (A_2).

patients with MS usually are precipitated by tachycardia resulting from exercise, pregnancy, hyperthyroidism, anemia, infection, or AF. All these (1) increase the rate of blood flow across the mitral orifice, resulting in further elevation of the left atrial pressure, and (2) decrease the diastolic filling time, resulting in a reduction in forward cardiac output. Because diastole shortens proportionately more than systole as heart rate increases, the time available for flow across the mitral valve is reduced at higher heart rates. At any given stroke volume, therefore, tachycardia results in a higher instantaneous volume flow rate and higher transmitral pressure gradient, which elevates left atrial pressures further. This higher transmitral gradient, often in combination with inadequate ventricular filling (because of the shortened diastolic filling time), explains the sudden occurrence of dyspnea and pulmonary edema in previously asymptomatic patients with MS who develop AF with a rapid ventricular rate. It also accounts for the equally rapid clinical improvement in these patients when the ventricular rate is slowed.

Atrial contraction augments the presystolic transmitral valvular gradient by approximately 30% in patients with MS (see Figs. 63-22 and 19-14). AF is common in patients with MS, with an increasing prevalence with age. In patients with severe MS younger than 30 years, only approximately 10% are in AF, compared with approximately 50% of those older than 50 years. Withdrawal of atrial transport when AF develops reduces cardiac output by approximately 20%, often resulting in symptom onset.

Obstruction at the mitral valve level has other hemodynamic consequences, which account for many of the adverse clinical outcomes associated with this disease. Elevated left atrial pressure results in pulmonary artery hypertension, with secondary effects on the pulmonary vasculature and right side of the heart. In addition, left atrial enlargement and stasis of blood flow is associated with an increased risk of thrombus formation and systemic embolism. Typically, the left ventricle is relatively normal, unless there is coexisting MR, with the primary abnormalities of the left ventricle being a small underfilled chamber and paradoxical septal motion caused by RV enlargement and dysfunction.

Hemodynamic Consequences of Mitral Stenosis

PULMONARY HYPERTENSION. In patients with MS and sinus rhythm, mean left atrial pressure is elevated (see Fig. 63-22), and the

left atrial pressure curve shows a prominent atrial contraction (a wave), with a gradual pressure decline after mitral valve opening (y descent). In patients with mild to moderate MS without elevated pulmonary vascular resistance, pulmonary arterial pressure may be normal or only minimally elevated at rest but rises during exercise. However, in patients with severe MS and those in whom the pulmonary vascular resistance is significantly increased, pulmonary arterial pressure is elevated when the patient is at rest. Rarely, in patients with extremely elevated pulmonary vascular resistance, pulmonary arterial pressure may exceed systemic arterial pressure. Further elevations of left atrial and pulmonary vascular pressures occur during exercise and/or tachycardia.

Pulmonary hypertension in patients with MS results from the following: (1) passive backward transmission of the elevated left atrial pressure; (2) pulmonary arteriolar constriction, which presumably is triggered by left atrial and pulmonary venous hypertension (reactive pulmonary hypertension); and (3) organic obliterative changes in the pulmonary vascular bed, which may be considered to be a complication of longstanding and severe MS (see Chapter 74). With moderately elevated pulmonary arterial pressure (systolic pressure 30 to 60 mm Hg), RV performance is usually maintained. In time, severe pulmonary hypertension results in right-sided heart failure, with dilation of the right ventricle and its annulus, secondary tricuspid regurgitation (TR), and sometimes pulmonic regurgitation. These changes in the pulmonary vascular bed may also exert a protective effect; the elevated precapillary resistance makes the development of symptoms of pulmonary congestion less likely to occur by tending to prevent blood from surging into the pulmonary capillary bed and damming up behind the stenotic mitral valve. This protection, however, occurs at the expense of a reduced cardiac output. In patients with severe MS, pulmonary vein–bronchial vein shunts occur. Their rupture may cause hemoptysis. Patients with severe MS exhibit a reduction in pulmonary compliance, increase in the work of breathing, and redistribution of pulmonary blood flow from the base to the apex.

LEFT VENTRICULAR FUNCTION. The LV chamber typically is normal or small, with normal systolic function and normal LV end-diastolic pressure. However, coexisting MR, aortic valve lesions, systemic hypertension, ischemic heart disease, and cardiomyopathy all may be responsible for elevations of LV diastolic pressure.

EXERCISE HEMODYNAMICS. At any given severity of stenosis, the clinical picture is dictated largely by the levels of cardiac output and pulmonary vascular resistance with exertion. The response to a given degree of mitral obstruction may be characterized at one end of the hemodynamic spectrum by a normal cardiac output and high left atrioventricular pressure gradient or, at the opposite end of the spectrum, by a markedly reduced cardiac output and low transvalvular pressure gradient. Thus, in some patients with moderate MS (with a mitral valve area of 1.0 to 1.5 cm^2), cardiac output may be normal at rest and rises normally during exertion. However, the high transvalvular pressure gradient with exertion elevates left atrial and pulmonary capillary pressures, leading to pulmonary congestion during exertion. By contrast, in other patients with moderate MS, there is an inadequate rise in cardiac output during exertion, resulting in a smaller rise in pulmonary venous pressure. In these patients, symptoms are caused by a low cardiac output rather than by pulmonary congestion. In patients with severe MS (mitral valve area $<1 \text{ cm}^2$), particularly when pulmonary vascular resistance is elevated, cardiac output usually is depressed at rest and may fail to rise at all during exertion. These patients frequently have resting weakness and fatigue secondary to a low cardiac output, with low-output and pulmonary congestion symptoms with exercise.

LEFT ATRIAL CHANGES. The combination of mitral valve disease and atrial inflammation secondary to rheumatic carditis causes (1) left atrial dilation, (2) fibrosis of the atrial wall, and (3) disorganization of the atrial muscle bundles. These changes lead to disparate conduction velocities and inhomogeneous refractory periods.¹⁶³ Premature atrial activation, caused by an automatic focus or reentry, may stimulate the left atrium during the vulnerable period, thereby precipitating AF. The development of this arrhythmia

correlates independently with the severity of the MS, degree of left atrial dilation, and height of the left atrial pressure. However, in most studies of patients with severe MS undergoing percutaneous balloon mitral valvotomy (BMV), the strongest predictor of AF is older age. AF often is episodic at first but then becomes more persistent. AF per se causes diffuse atrophy of atrial muscle, further atrial enlargement, and further inhomogeneity of refractoriness and conduction. These changes lead in turn to irreversible AF.

Clinical Presentation

Symptoms. *Dyspnea.* The most common presenting symptoms of MS are dyspnea, fatigue, and decreased exercise tolerance.¹⁵⁷ Symptoms may be caused by a reduced ability to increase cardiac output normally with exercise or elevated pulmonary venous pressures and reduced pulmonary compliance. Dyspnea may be accompanied by cough and wheezing. Vital capacity is reduced, presumably because of the presence of engorged pulmonary vessels and interstitial edema. Patients who have critical obstruction to left atrial emptying and dyspnea with ordinary activity (NYHA functional class III) generally have orthopnea as well and are at risk for attacks of frank pulmonary edema. The latter may be precipitated by effort, emotional stress, respiratory infection, fever pregnancy, or AF with a rapid ventricular rate or other tachyarrhythmia. Pulmonary edema may be caused by any condition that increases the flow rate across the stenotic mitral valve, either because of an increase in total cardiac output or a reduction in the time available for blood flow across the mitral orifice to occur. In patients with a markedly elevated pulmonary vascular resistance, RV function often is impaired, and the presentation also may include symptoms and signs of right-heart failure.

MS is a slowly progressive disease, and many patients remain seemingly asymptomatic merely by readjusting their lifestyles to a more sedentary level. Usually, symptom status can be accurately assessed by a directed history, asking the patient to compare current levels of maximum exertion with those at specific time points in the past. Exercise testing may be useful for selected patients to determine functional status in an objective manner and may be combined with Doppler echocardiography (see later) to assess exercise hemodynamics.

Hemoptysis. Hemoptysis is rare in patients with a known diagnosis of MS because intervention usually is performed before severe obstruction becomes chronic. When hemoptysis does occur, it can be sudden and severe, caused by rupture of thin-walled, dilated bronchial veins, usually as a consequence of a sudden rise in left atrial pressure, or it may be milder, with only blood-stained sputum associated with attacks of paroxysmal nocturnal dyspnea. The pink frothy sputum characteristic of acute pulmonary edema with rupture of alveolar capillaries also may develop in these patients. Hemoptysis also may be caused by pulmonary infarction, a late complication of MS associated with heart failure.

Chest Pain. Chest pain is not a typical symptom of MS, but a small proportion, perhaps 15%, of patients with MS experience chest discomfort that is indistinguishable from that of angina pectoris. This symptom may be caused by severe RV hypertension secondary to the pulmonary vascular disease or by concomitant coronary atherosclerosis. Rarely, chest pain may be secondary to coronary obstruction caused by coronary embolization. In many patients, however, a satisfactory explanation for the chest pain cannot be uncovered, even after complete hemodynamic and angiographic studies.

Palpitations and Embolic Events. Patients with MS often are initially diagnosed when they present with AF or an embolic event.

Other Symptoms. Compression of the left recurrent laryngeal nerve by a greatly dilated left atrium, enlarged tracheobronchial lymph nodes, and dilated pulmonary artery may cause hoarseness (Ortner syndrome). A history of repeated hemoptysis is common in patients with pulmonary hemosiderosis. Systemic venous hypertension, hepatomegaly, edema, ascites, and hydrothorax are all signs of severe MS with elevated pulmonary vascular resistance and right-sided heart failure.

Physical Examination. The most common findings on physical examination in patients with MS are an irregular pulse caused by AF and signs of left- and right-heart failure (see Chapter 11). The classic diastolic murmur and loud first heart sound often are difficult to appreciate. Patients with severe chronic MS, a low cardiac output, and systemic vasoconstriction may exhibit the so-called mitral facies, characterized by pinkish-purple patches on the cheeks. The arterial pulse is usually normal, but in patients with a reduced stroke volume, the

pulse may be low in volume. The jugular venous pulse usually exhibits a prominent a wave in patients with sinus rhythm and elevated pulmonary vascular resistance. In patients with AF, the x descent of the jugular venous pulse disappears, and there is only one crest, a prominent v or c-v wave, per cardiac cycle. Palpation of the cardiac apex usually reveals an inconspicuous left ventricle; the presence of a palpable presystolic expansion wave or an early diastolic rapid filling wave speaks strongly against serious MS. A readily palpable, tapping S₁ suggests that the anterior mitral valve leaflet is pliable. When the patient is in the left lateral recumbent position, a diastolic thrill of MS may be palpable at the apex. Often, a RV lift is felt in the left parasternal region in patients with pulmonary hypertension. A markedly enlarged right ventricle may displace the left ventricle posteriorly and produce a prominent RV apex beat that can be confused with a LV lift. A loud P₂ may be palpable in the second left intercostal space in patients with MS and pulmonary hypertension.

Auscultation. The auscultatory features of MS (see Fig. 63-22) include an accentuated S₁ with prolongation of the Q-S₁ interval, correlating with the level of the left atrial pressure. Accentuation of S₁ occurs when the mitral valve leaflets are flexible. It is caused in part by the rapidity with which LV pressure rises at the time of mitral valve closure, as well as by the wide closing excursion of the leaflets. Marked calcification and/or thickening of the mitral valve leaflets reduce the amplitude of S₁, probably because of diminished motion of the leaflets. As pulmonary arterial pressure rises, P₂ at first becomes accentuated and widely transmitted and often can be readily heard at both the mitral and the aortic areas. With further elevation of pulmonary arterial pressure, splitting of S₂ narrows because of reduced compliance of the pulmonary vascular bed, with earlier pulmonic valve closure. Finally, S₂ becomes single and accentuated. Other signs of severe pulmonary hypertension include a nonvalvular pulmonic ejection sound that diminishes during inspiration, because of dilation of the pulmonary artery, a systolic murmur of TR, a Graham Steell murmur of pulmonic regurgitation, and a S₄ originating from the right ventricle. An S₃ gallop originating from the left ventricle is absent in patients with MS unless significant MR or AR coexists.

The opening snap (OS) of the mitral valve is caused by a sudden tensing of the valve leaflets after the valve cusps have completed their opening excursion. The OS occurs when the movement of the mitral dome into the left ventricle suddenly stops. It is most readily audible at the apex, using the diaphragm of the stethoscope. The OS usually can be differentiated from P₂ because the OS occurs later, unless right bundle branch block is present. In addition, the OS usually is loudest at the apex, whereas S₂ is best heard at the cardiac base. The mitral valve cannot be totally rigid if it produces an OS, so an OS usually is accompanied by an accentuated S₁. Calcification confined to the tip of the mitral valve leaflets does not preclude an OS, although calcification of the body and tip does. The mitral OS follows A₂ by 0.04 to 0.12 second; this interval varies inversely with the left atrial pressure. A short A₂-OS interval is a reliable indicator of severe MS but accurate estimation of this time interval requires considerable experience.

The diastolic, low-pitched, rumbling murmur of MS is best heard at the apex, with the bell of the stethoscope (low-frequency mode on electronic stethoscopes) and with the patient in the left lateral recumbent position. When this murmur is soft, it is limited to the apex but, when louder, it may radiate to the left axilla or the lower left sternal area. Although the intensity of the diastolic murmur is not closely related to the severity of stenosis, the duration of the murmur is a guide to the severity of mitral valve narrowing. The murmur persists for as long as the left atrioventricular pressure gradient exceeds approximately 3 mm Hg. The murmur usually commences immediately after the OS. In mild MS, the early diastolic murmur is brief but, in the presence of sinus rhythm, it resumes in presystole. In severe MS, the murmur persists until end-diastole, with presystolic accentuation while sinus rhythm is maintained (see Figs. 63-22 and 11-8F).

Other Auscultatory Findings. A pansystolic murmur of TR and a S₃ originating from the right ventricle may be audible in the fourth intercostal space in the left parasternal region in patients with severe MS. These signs, which are secondary to pulmonary hypertension, may be confused with the findings of MR. However, the inspiratory augmentation of the murmur and of the S₃ and the prominent v wave in the jugular venous pulse aid in establishing that the murmur originates from the tricuspid valve. A high-pitched decrescendo diastolic murmur along the left sternal border in patients with MS and pulmonary hypertension may be audible pulmonic regurgitation (Graham Steell murmur) but more often is caused by concomitant AR.

Diagnosis and Evaluation

Differential Diagnosis

MS is a rare diagnosis in developed countries, and most apical diastolic murmurs have other causes. In older patients, an apical diastolic rumble is most likely to be caused by mitral annular calcification, and 90% of patients with a diastolic apical murmur have no evidence of MS on echocardiography. In severe MR—indeed, in any condition in which flow across a nonstenotic mitral valve is increased (e.g., a ventricular septal defect)—there may also be a short diastolic murmur following a S₃. Left atrial myxoma (see Chapter 85) may produce auscultatory findings similar to those in rheumatic valvular MS. A diastolic rumble may also be present in some patients with HCM, caused by early diastolic flow into the hypertrophied, nondistensible left ventricle (see Chapter 66).

Echocardiography

Echocardiography is the most accurate approach to the diagnosis and evaluation of MS (see Chapter 14).^{38,162} It is recommended for all patients with MS at initial presentation, for reevaluation of changing symptoms or signs, and at regular intervals (depending on disease severity) for monitoring disease progression (see Table 63-7). Imaging shows the characteristic anatomy with leaflet thickening and restriction of opening caused by symmetric fusion of the commissures, resulting in “doming” of the leaflets in diastole (see Fig. 63-21; see also Fig. 14-37; Videos 63-9A and 63-10A). As disease becomes more severe, thickening extends from the leaflet tips toward the base, with further restriction of motion and less curvature of the leaflet in diastole. The mitral chords are variably thickening, fused, and shortened, with superimposed calcification of the valve apparatus in some cases.

Mitral valve area is measured by direct planimetry from two-dimensional short-axis images (see Fig. 63-21, right; see also Fig. 14-38; Videos 63-9B and 63-10B) and calculated by the Doppler pressure half-time and PISA (proximal isovelocity surface area) methods (see Figs. 14-39 and 14-40; Video 63-11).¹⁶⁴ The transmitral gradient also is calculated and any coexisting MR is quantitated on the basis of the accepted guidelines.^{22,165} Three-dimensional echocardiography is playing an increasing role in assessing mitral valve morphology and quantifying severity of MS (see Fig. 14-38; Videos 63-12A and 63-12B).¹⁶⁶⁻¹⁷⁰ Evaluation of the morphology of the valve is helpful for predicting the hemodynamic results and outcome of percutaneous BMV. A score of 0 to 4+ is given for leaflet thickness, mobility, calcification, and chordal involvement to provide an overall score that is favorable (low) or unfavorable (high) for valvuloplasty (see Table 14-10). Other important anatomic features of the valve are the degree of anterior leaflet doming, symmetry of commissural fusion, and distribution of leaflet calcification.¹⁶²

Other key features on echocardiography are left atrial size, pulmonary artery pressures, LV size and systolic function, and RV size and systolic function. When pulmonary hypertension is present, the right ventricle frequently is dilated, with reduced systolic function. TR may be secondary to RV dysfunction and annular dilation or may be caused by rheumatic involvement of the tricuspid valve. Complete evaluation of aortic valve anatomy and function also is important because the aortic valve is affected in approximately one third of patients with MS. When transthoracic images are suboptimal, TEE is appropriate. TEE also is necessary to exclude left atrial thrombus and to evaluate MR severity when percutaneous BMV is considered.

Exercise Testing with Doppler Echocardiography

Exercise testing is useful for many patients with MS to ascertain the level of physical conditioning and elicit covert cardiac symptoms. The exercise test can be combined with Doppler echocardiography to assess exercise pulmonary pressure,^{93,162} usually with the Doppler examination performed at rest after termination of exercise. Exercise Doppler testing is recommended when there is a discrepancy between resting echocardiographic findings and the severity of clinical symptoms.^{1,33} Useful parameters on exercise testing include the following: (1) exercise duration; (2) blood pressure and heart rate response; and (3) increase in pulmonary pressures with exercise, compared with the expected normal changes. An exercise

Three-dimensional transesophageal echocardiography of mitral stenosis. Severe mitral stenosis with more prominent fusion of the lateral, compared to medial, commissure is seen from the left atrial aspect of the valve (**A**) and from the perspective of the left ventricular side of the valve (**B**). (From Otto CM: *Echocardiographic evaluation of valvular heart disease*. In Otto CM, Bonow RO, editors. *Valvular Heart Disease: A Companion to Braunwald's Heart Disease*, 4th ed. Philadelphia, Saunders, 2014.)

pulmonary systolic pressure greater than 60 mm Hg is a key decision point in the management of these patients.

Other Diagnostic Evaluation Modalities

Electrocardiography. The ECG is relatively insensitive for detecting mild MS, but it does show characteristic changes in moderate or severe obstruction (see Chapter 12). Left atrial enlargement (P wave duration in lead II >0.12 second and/or a P wave axis between +45 and -30 degrees) is a principal electrocardiographic feature of MS and is found in 90% of patients with significant MS and sinus rhythm. The electrocardiographic signs of left atrial enlargement correlate more closely with left atrial volume than with left atrial pressure and often regress after successful valvotomy. AF is common with longstanding MS, as noted.

Electrocardiographic evidence of RV hypertrophy correlates with RV systolic pressure. When RV systolic pressure is 70 to 100 mm Hg, approximately 50% of patients exhibit ECG criteria for RV hypertrophy, including a mean QRS axis greater than 80 degrees in the frontal plane and a R:S ratio greater than 1 in lead V₁. Other patients with this degree of pulmonary hypertension have no frank evidence of RV hypertrophy, but the R:S ratio fails to increase from the right to the midprecordial leads. When RV systolic pressure is greater than 100 mm Hg in patients with isolated or predominant MS, electrocardiographic evidence of RV hypertrophy is consistently found.

Radiography. Patients with hemodynamically significant MS almost invariably have evidence of left atrial enlargement on the lateral and left anterior oblique views (see Fig. 15-10), although the cardiac silhouette may be normal in the frontal projection. Extreme left atrial enlargement rarely occurs in isolated MS; when present, MR usually is severe (see Fig. 15-8). Enlargement of the pulmonary artery, right ventricle, and right atrium (as well as the left atrium) is commonly seen in patients with severe MS. Occasionally, calcification of the mitral valve is evident on the chest roentgenogram but, more commonly, fluoroscopy is required to detect valvular calcification.

Radiologic changes in the lung fields indirectly reflect the severity of MS (see Chapter 15). Interstitial edema, an indication of severe obstruction, is manifested as Kerley B lines (dense, short, horizontal lines most commonly seen in the costophrenic angles). This finding is present in 30% of patients with resting pulmonary arterial wedge pressures less than 20 mm Hg and in 70% of patients with pressures greater than 20 mm Hg. Severe longstanding mitral obstruction often results in Kerley A lines (straight, dense lines up to 4 cm in length, running toward the hilum), as well as the findings of pulmonary hemosiderosis and rarely of parenchymal ossification.

Cardiac Catheterization. Catheter-based measurement of left atrial and LV pressures shows the expected hemodynamics (see Fig. 19-14) and allows measurement of the mean transmitral pressure gradient and, in conjunction with measurement of transmitral volume flow rate, calculation of the valve area using the Gorlin formula (see Chapter 19). Occasionally, diagnostic cardiac catheterization is necessary when echocardiography is nondiagnostic or results are discrepant with clinical findings.¹⁷¹ More often, these measurements now are recorded for monitoring before, during, and after percutaneous BMV. Routine diagnostic cardiac catheterization is not recommended for the evaluation of MS.

Disease Course

Interval Between Acute Rheumatic Fever and Mitral Valve Obstruction

In temperate zones, such as the United States and Western Europe, patients who develop acute rheumatic fever have an asymptomatic period of approximately 15 to 20 years before symptoms of MS develop (see Fig. e63-2). It then takes approximately 5 to 10 years for most patients to progress from mild disability (i.e., early NYHA class II) to severe disability (i.e., NYHA functional class III or IV). The progression is much more rapid in patients in tropical and subtropical areas, in Polynesians, and in Native Alaskans. In India, critical MS may be present in children as young as 6 to 12 years of age. In North America and Western Europe, however, symptoms develop more slowly, with onset commonly between the ages of 45 and 65 years. The most likely causes for these differences are the relative prevalence of rheumatic fever and lack of primary and secondary prevention in developing countries, resulting in recurrent episodes of valve scarring (see Chapter 83).

Hemodynamic Progression

Serial echocardiographic data have described the rate of hemodynamic progression in patients with mild MS.^{157,162} The two largest series comprised a combined total of 153 adults, with a mean age of approximately 60 years, with an average follow-up period of slightly more than 3 years. As in most series of patients with MS, 75% to 80% were women. The initial valve area was 1.7 ± 0.6 cm², and the overall rate of progression was a decrease in valve area of 0.09 cm²/year. Approximately one third of patients showed rapid progression, defined as a decrease in valve area greater than 0.1 cm²/year. These data apply to the older patients with MS seen in developed countries. There are little data on the rate of hemodynamic progression of rheumatic MS in underdeveloped countries, in which the age at symptom onset is much younger.

Clinical Outcomes

Natural history data obtained in the presurgical era indicate that symptomatic patients with MS have a poor outlook, with 5-year survival rates of 62% among patients with MS in NYHA class III but only 15% among those in class IV. Data from unoperated patients in the surgical era still reported a 5-year survival rate of only 44% in patients with symptomatic MS who refused valvotomy (Fig. 63-23).

Overall clinical outcomes are greatly improved in patients who undergo surgical or percutaneous relief of valve obstruction on the basis of current guidelines.^{1,2} However, longevity is still shortened compared with that expected for age, largely because of complications of the disease process (AF, systemic embolism, pulmonary hypertension) and side effects of therapy (e.g., prosthetic valves, anticoagulation).

Complications

ATRIAL FIBRILLATION. The most common complication of MS is AF (see Chapter 38).¹⁵⁷ The prevalence of AF in patients with MS is related to the severity of valve obstruction and patient age. In historical series, AF was present in 17% of patients 21 to 30 years of age, 45% of those 31 to 40 years, 60% of those 41 to 50 years, and 80% of those older than 51 years. Even when MS is severe, the prevalence of AF is related to age. In more recent BMV studies, the prevalence of AF ranged from 4% in a series of 600 patients from India, with a mean age of 27 years, and 27% in a series of 4832 patients from China, with a mean age of 37 years, to 40% in a series of 1024 patients from France, with a mean age of 49 years.

FIGURE 63-23 Natural history of the respective valvular lesion in 159 patients with isolated MS (solid blue line) or MR (solid purple line) who were not operated on, even though the operation was indicated, compared with patients treated with valve replacement for mitral stenosis (dashed blue line) or mitral regurgitation (dashed purple line). The expected survival rate in the absence of mitral valve disease is indicated by the upper curve (dashed black line). (From Horstkotte D, Niehues R, Strauer BE: Pathomorphological aspects, aetiology, and natural history of acquired mitral valve stenosis. *Eur Heart J* 12[Suppl B]:55, 1991.)

FIGURE e63-2 Interval between active rheumatic fever and clinical symptoms of valve disease in 177 patients with mitral stenosis (yellow bars) and 121 with aortic stenosis (blue bars). (From Horstkotte D, Niehues R, Strauer BE: *Pathomorphological aspects, aetiology, and natural history of acquired mitral valve stenosis*. *Eur Heart J* 12[suppl B]:55, 1991.)

AF may precipitate or worsen symptoms caused by loss of the atrial contribution to filling and to a short diastolic filling period when the ventricular rate is not well controlled. In addition, AF predisposes affected patients to left atrial thrombus formation and systemic embolic events. AF conveys a worse overall prognosis in MS patients than in the general population. In patients with AF and MS, 5-year survival is only 64%, compared with 85% in patients with AF but without MS.

SYSTEMIC EMBOLISM. Systemic embolism in patients with MS is caused by left atrial thrombus formation. Although systemic embolization most often occurs in patients with AF, 20% of patients with MS and a systemic embolic event are in sinus rhythm. When embolization occurs in patients in sinus rhythm, the possibility of transient AF or underlying infective endocarditis should be considered. However, up to 45% of patients with MS who are in normal sinus rhythm demonstrate prominent spontaneous left atrial (Video 63-13) contrast (a marker of embolic risk) on TEE (see Chapter 14). Atrial thrombi have been documented in a few patients with MS in sinus rhythm, and many patients with new-onset AF have left atrial thrombi. It is postulated that the loss of atrial appendage contractile function, despite electrical evidence of sinus rhythm, leads to blood flow stasis and thrombus formation. Additional evidence implicates inflammatory markers, endothelial dysfunction, and platelet activation as inciting mechanisms for thromboembolism.^{172,173}

The risk of embolism correlates directly with patient age and left atrial size¹⁷⁴ and inversely with the cardiac output. Before the advent of surgical treatment, this serious complication of MS developed in at least 20% of patients at some time during the course of their disease. Before the era of anticoagulant therapy and surgical treatment, approximately 25% of all fatalities in patients with mitral valve disease were secondary to systemic embolism.

Approximately half of all clinically apparent emboli are found in the cerebral vessels. Coronary embolism may lead to myocardial infarction and/or angina pectoris, and renal emboli may be responsible for the development of systemic hypertension. Emboli are recurrent and multiple in approximately 25% of patients who develop this complication. Rarely, massive thrombosis develops in the left atrium, resulting in a pedunculated ball valve thrombus, which may suddenly aggravate obstruction to left atrial outflow when a specific body position is assumed or may cause sudden death. Similar consequences occur in patients with free-floating thrombi in the left atrium. These two conditions usually are characterized by variability in the physical findings, often on a positional basis. They are very hazardous and necessitate surgical treatment, often on an emergency basis.

INFECTIVE ENDOCARDITIS. MS is a predisposing factor for endocarditis (see Chapter 64) in less than 1% of cases in clinical series of bacterial endocarditis. The estimated risk of endocarditis in patients with MS is 0.17/1000 patient-years, which is much lower than the risk in patients with MR or aortic valve disease.

Medical Management

Drug Treatment. The medical management of MS is directed primarily toward the following: (1) prevention of recurrent rheumatic fever; (2) prevention and treatment of complications of MS; and (3) monitoring disease progression to allow intervention at the optimal time point.¹⁵⁷ Patients with MS caused by rheumatic heart disease should receive penicillin prophylaxis for beta-hemolytic streptococcal infections to prevent recurrent rheumatic fever, per established guidelines (see Chapter 83). Prophylaxis for infective endocarditis is no longer recommended (see Chapter 64). Anemia and infections should be treated promptly and aggressively in patients with valvular heart disease. Of note, however, blood cultures should always be considered before initiation of antibiotic therapy in patients with valve disease, because the presentation of endocarditis often is mistaken for a noncardiac infection.

Anticoagulant therapy is indicated for prevention of systemic embolism in patients with MS and AF (persistent or paroxysmal), any previous embolic events (even if in sinus rhythm), and documented left atrial thrombus. Anticoagulation also may be considered for patients with severe MS and sinus rhythm when there is severe left atrial enlargement (diameter >55 mm) or spontaneous contrast on echocardiography. Treatment with warfarin is used to maintain the international normalized ratio (INR) between 2 and 3.¹⁷⁵

Asymptomatic patients with mild to moderate rheumatic mitral valve disease should have a history and physical examination annually, with echocardiography every 3 to 5 years for mild stenosis, every 1 to 2 years for moderate stenosis, and annually for severe stenosis. More frequent evaluation is appropriate for any change in signs or symptoms. All patients with significant MS should be advised to avoid occupations requiring strenuous exertion.

In patients with severe MS, with persistent symptoms after intervention or when intervention is not possible, medical therapy with oral diuretics and the restriction of sodium intake may improve symptoms. Digitalis glycosides do not alter the hemodynamics and usually do not benefit patients with MS and sinus rhythm, but these drugs are of value in slowing the ventricular rate in patients with AF and in treating patients with right-sided heart failure. Hemoptysis is managed by measures designed to reduce pulmonary venous pressure, including sedation, assumption of the upright position, and aggressive diuresis. Beta-adrenergic blocking agents and rate-slowing calcium antagonists may increase exercise capacity by reducing heart rate in patients with sinus rhythm, especially in patients with AF.

Treatment of Arrhythmias. AF is a frequent complication of severe MS. Management of AF for patients with MS is similar to management for AF of any cause (see Chapter 38). However, it typically is more difficult to restore and maintain sinus rhythm because of pressure overload of the left atrium in conjunction with effects of the rheumatic process on atrial tissue and the conducting system.

Immediate treatment of AF includes administration of intravenous heparin followed by oral warfarin. The ventricular rate should be slowed, as stated in the American College of Cardiology/American Heart Association (ACC/AHA) guidelines for the management of AF,¹⁷⁵ initially with an intravenous beta blocker or nondihydropyridine calcium channel antagonist, followed by long-term rate control with oral doses of these agents. When these medications are ineffective or when additional rate control is necessary, digoxin or amiodarone may be considered. Digoxin alone for long-term management of AF may be considered in patients with concurrent LV dysfunction or a sedentary lifestyle. An effort should be made to reestablish sinus rhythm by a combination of pharmacologic treatment and cardioversion. If cardioversion is planned in a patient who has had AF for more than 24 hours before the procedure, anticoagulation with warfarin for more than 3 weeks is indicated. Alternatively, if TEE results show no atrial thrombus, immediate cardioversion can be carried out provided the patient is effectively anticoagulated with intravenous heparin before and during the procedure, and with warfarin chronically thereafter. Paroxysmal AF and repeated conversions, spontaneous or induced, carry the risk of embolization. In patients who cannot be converted or maintained in sinus rhythm, digitalis should be used to maintain the ventricular rate at rest at approximately 60 beats/min. If this is not possible, small doses of a beta-adrenergic blocking agent, such as atenolol (25 mg daily) or metoprolol (50 to 100 mg daily), may be added. Beta blockers are particularly helpful in preventing rapid ventricular responses that develop during exertion. Multiple repeat cardioversions are not indicated if the patient fails to sustain sinus rhythm while on adequate doses of an antiarrhythmic.

Patients with chronic AF who undergo surgical mitral valve repair or replacement may undergo the maze procedure (atrial compartment operation). More than 80% of patients undergoing this procedure can be maintained in sinus rhythm postoperatively and can regain normal atrial function, including a satisfactory success rate in those with significant left atrial enlargement. Early intervention with percutaneous valvotomy may prevent the development of AF.¹⁷⁶

Mitral Valvotomy

Percutaneous Balloon Mitral Valvotomy

Patients with mild to moderate MS who are asymptomatic frequently remain so for years, and clinical outcomes are similar to those in age-matched normal subjects. Severe or symptomatic MS, however, is associated with poor long-term outcomes if the stenosis is not relieved mechanically (see Fig. 63-23). Percutaneous BMV (see Chapter 56) is the procedure of choice for the treatment of MS; surgical intervention is now reserved for patients who require intervention and are not candidates for a percutaneous procedure.¹⁵⁷

BMV is recommended for symptomatic patients with moderate to severe MS (i.e., a mitral valve area <1 cm²/m² of body surface area [BSA] or <1.5 cm² in normal-sized adults) and with favorable valve morphology, no or mild MR, and no evidence of left atrial

**VIDEO 63-13**

Spontaneous left atrial contrast. On this transesophageal echocardiography image, swirling spontaneous contrast is seen in the enlarged left atrium of a patient with severe mitral stenosis. thrombus (Fig. 63-24). Even mild symptoms, such as a subtle decrease in exercise tolerance, are an indication for intervention because the procedure relieves symptoms and improves long-term outcome with a low procedural risk. In addition, BMV is a reasonable option for asymptomatic patients with very severe MS ($< 1 \text{ cm}^2$) with favorable valve anatomy or when mitral valve obstruction has resulted in AF. Of note, AF precipitates symptoms in most patients with significant MS.

BMV also may be considered in symptomatic patients in whom surgery carries high risk for adverse events or outcomes, even when valve morphology is not ideal, including patients with restenosis after a previous BMV or previous commissurotomy who are unsuitable candidates for surgery because of very high risk. These include very old, frail patients; patients with associated severe ischemic heart disease; patients in whom MS is complicated by pulmonary, renal, or neoplastic disease; women of childbearing age in whom mitral valve replacement is undesirable; and pregnant women with MS.

BMV may be further considered for patients with mild MS in whom symptoms cannot be explained by other causes and who experience pulmonary hypertension ($> 25 \text{ mm Hg}$) with exercise (see Fig. 63-24). In this last group, it is likely that valve obstruction is the cause of pulmonary hypertension, even when stenosis severity does not meet the valve area criteria for severe obstruction.

This percutaneous technique consists of advancing a small balloon flotation catheter across the interatrial septum (after transseptal puncture), enlarging the opening, advancing a large (23- to 25-mm) hourglass-shaped balloon (the Inoue balloon), and inflating it within the orifice¹⁷⁶⁻¹⁷⁸ (Fig. 63-25, Videos 63-14A, 63-14B, and 63-14C). Alternatively, two smaller (15- to 20-mm) side-by-side balloons across the

mitral orifice may be used. A third technique involves retrograde, nontransseptal dilation of the mitral valve, in which the balloon is positioned across the mitral valve using a steerable guidewire.

Commissural separation and fracture of nodular calcium appear to be the mechanisms responsible for improvement in valvular function. In several series, the hemodynamic results of BMV have been favorable (Fig. 63-26), with reduction of the transmitral pressure gradient from an average of approximately 18 to 6 mm Hg (see Chapter 56), a small (average, 20%) increase in cardiac output, and an average doubling of the calculated mitral valve area, from 1 to 2 cm^2 .^{157,171,177} Results are especially impressive in younger patients without severe valvular thickening or calcification (see Fig. 63-21). Elevated pulmonary vascular resistance declines rapidly, although usually not completely. The reported mortality rate has ranged from 1% to 2%. Complications include cerebral emboli and cardiac perforation, each in approximately 1% of patients, and the development of MR severe enough to require operation in another 2% (approximately 15% develop lesser, but still undesirable, degrees of MR).¹⁷⁹ Approximately 5% of patients are left with a small residual atrial septal defect, but this closes or decreases in size in most. Rarely, the defect is large enough to cause right-sided heart failure; this complication most often is seen in conjunction with an unsuccessful mitral valvotomy.

The likelihood of hemodynamic benefit and the risk of complication with BMV are predicted by anatomic features of the stenosed valve (Videos 63-15A and 63-15B). Rigid thickened valves with extensive subvalvular fibrosis and calcification lead to suboptimal results. One echocardiographic scoring system divides patients into three groups: those with a pliable, noncalcified anterior leaflet and little chordal disease—group 1; those with a pliable, noncalcified anterior

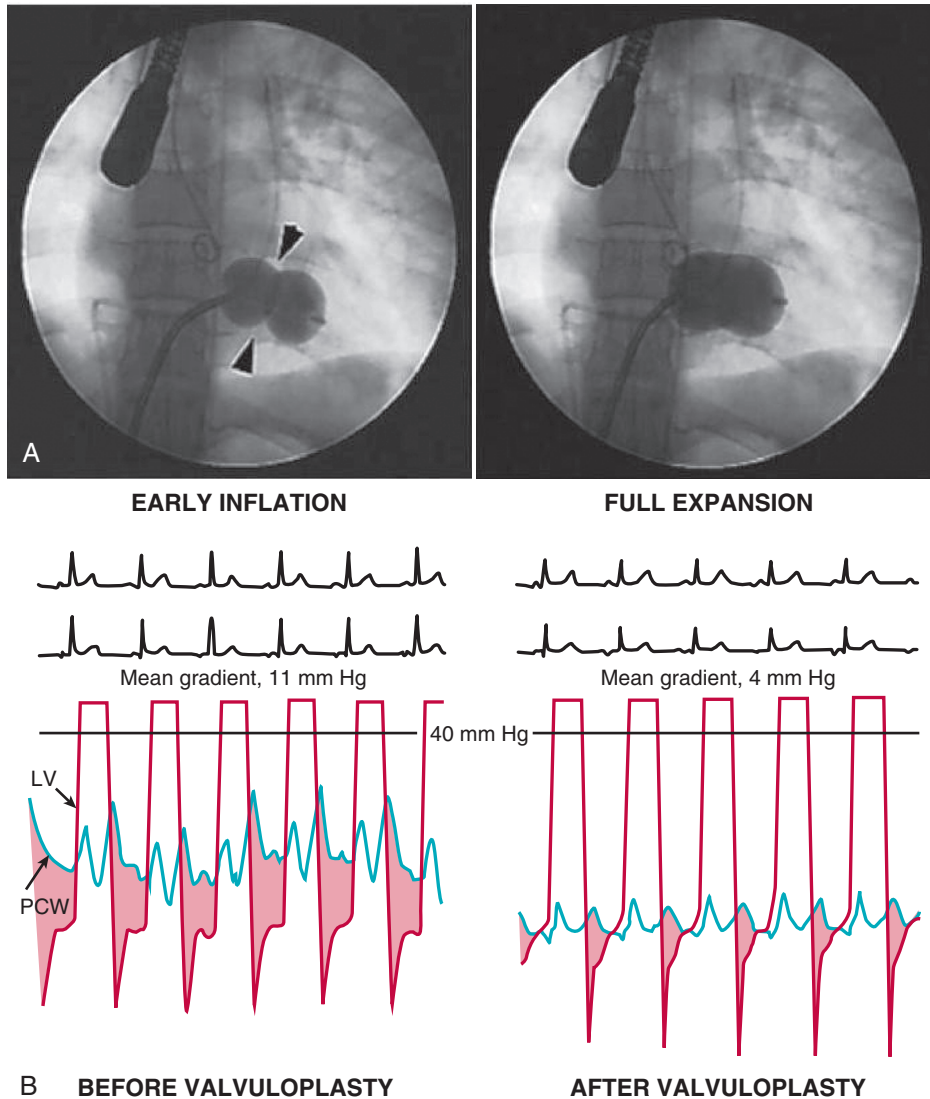

FIGURE 63-25 Percutaneous BMV for mitral stenosis using the Inoue technique (see Chapter 56). **A**, The catheter is advanced into the left atrium using the transeptal technique and guided in antegrade fashion across the mitral orifice. As the balloon is inflated, its distal portion expands first; this is pulled back so that it fits snugly against the orifice (arrowheads). With further inflation, the proximal portion of the balloon expands to center the balloon within the stenotic orifice (left). Further inflation expands the central “waist” portion of the balloon (right), resulting in commissural splitting and enlargement of the orifice. **B**, Successful BMV results in significant increase in mitral valve area, as reflected by a reduction in the diastolic pressure gradient between left ventricle (magenta) and pulmonary capillary wedge (PCW) (blue) pressure, as indicated by the shaded area. (From Delabays A, Goy JJ: *Images in clinical medicine: Percutaneous mitral valvuloplasty*. *N Engl J Med* 345:e4, 2001.)

leaflet but with chordal thickening and shortening (<10 mm long)—group 2; and those with fluoroscopic evidence of calcification of any extent of the valve apparatus—group 3.^{157,162} Event-free survival at 3 years is highest for group 1 (89%), compared with group 2 (78%) or group 3 (65%). With an alternate echocardiographic scoring system, leaflet rigidity, leaflet thickening, valvular calcification, and subvalvular disease are each scored from 0 to 4 (see Table 14-10).^{1,157} A score of 8 or lower usually is associated with an excellent immediate and long-term result, whereas scores exceeding 8 are associated with less impressive results (Fig. 63-27), including increased risk of development of MR. Commissural calcification also is a predictor of poor outcomes.

TEE should be performed just before BMV to exclude left atrial thrombus and confirm that MR is not moderate or severe. TEE also is appropriate for the evaluation of MS severity and mitral valve morphology when transthoracic images are suboptimal, but the chordal apparatus is less well visualized compared with transthoracic imaging. During the procedure, transthoracic, transesophageal, or intracardiac echocardiography is used to monitor placement of the

catheters and balloon, assess hemodynamic results after each inflation, and detect complications such as MR.

In patients with suitable anatomic findings, long-term results are favorable, with excellent survival rates without functional disability or need for surgery or repeat BMV.^{157,176-178} A prospective randomized trial in which patients with severe MS were randomly assigned to undergo BMV, closed surgical valvotomy, or open surgical valvotomy had similar clinical outcomes with BMV and the open surgical technique that were superior to the results of the closed surgical valvotomy. After 7 years, mitral valve area was equivalent in the BMV and open surgery groups, both significantly greater than in the closed valvotomy group (see Fig. 63-26). In another randomized study that included older patients with less favorable valve morphology, compared with open surgical commissurotomy, patients randomly assigned to undergo BMV had a smaller increase in valve area and higher likelihood of restenosis (28% versus 18% at 4 years). Excellent results also have been reported in children and adolescents in developing nations, where patients tend to be younger. These young patients usually have pliable valves, which are ideal for BMV.

Surgical Valvotomy

Three operative approaches are available for the treatment of rheumatic MS: (1) closed mitral valvotomy using a transatrial or transventricular approach; (2) open valvotomy (i.e., valvotomy carried out under direct vision with the aid of cardiopulmonary bypass), which may be combined with other repair techniques, such as leaflet resection, chordal procedures, and annuloplasty when MR is present; and (3) mitral valve replacement (Table 63-8).¹⁸⁰ Surgical intervention for MS is recommended for patients with severe MS and significant symptoms (NYHA class III or IV) when BMV is not available, when BMV is contraindicated because of persistent left atrial thrombus or moderate to severe MR, or when the

valve is calcified and surgical risk is acceptable. The preferred surgical approach is valve repair (open valvotomy, with or without additional procedures) whenever possible. Surgery also is reasonable for patients with severe MS and severe pulmonary hypertension when BMV is not possible and may be considered for patients with moderate to severe MS with recurrent embolic events despite anticoagulation.

CLOSED MITRAL VALVOTOMY. Closed mitral valvotomy is rarely used in the United States today, having been replaced by BMV, which is more effective in patients who are candidates for closed mitral valvotomy. Closed mitral valvotomy is more popular in developing nations, where the expense of open heart surgery and even of balloon catheters for BMV is an important factor and where patients with MS are younger and therefore have more pliable valves. However, even in these nations, closed mitral valvotomy is being replaced by BMV.

This procedure is performed without cardiopulmonary bypass but with the aid of a transventricular dilator. It is an effective operation, provided that MR, atrial thrombosis, or valvular calcification is not serious and that chordal fusion and shortening are not severe.

FIGURE 63-26 Mitral valve area before and 6 months and 7 years after valvotomy in a prospective, randomized trial of BMV (yellow bars), open surgical mitral commissurotomy (OMC) (purple bars) and closed mitral commissurotomy (CMC) (blue bars). At 6 months and 7 years, the results with BMV were equivalent to those with OMC and superior to those with CMC. * $P < 0.001$ in comparison to the baseline value; † $P < 0.001$ for BMV versus CMC; ‡ $P < 0.001$ for OMC versus CMC. (From Ben Farhat B, Ayari M, Maatouk F, et al: Percutaneous balloon versus surgical closed and open mitral commissurotomy: Seven-year follow-up results of a randomized trial. *Circulation* 97:245, 1998.)

FIGURE 63-27 Long-term survival (top) and event-free survival (bottom) after BMV for 879 patients who were stratified by baseline echocardiographic morphology score of 8 or less (blue line) or more than 8 (gold line). Patients with the lower echocardiography score had a significantly better outcome initially and over the next 12 to 13 years. (From Palacios IF, Sanchez PL, Harrell LC, et al: Which patients benefit from percutaneous mitral balloon valvuloplasty? Prevalvuloplasty and postvalvuloplasty variables that predict long-term outcome. *Circulation* 105:1465, 2002.)

Echocardiography is useful for selecting suitable candidates for this procedure by identifying patients without valvular calcification or dense fibrosis. If possible, closed mitral valvotomy should be carried out with pump standby; if the surgeon is unable to achieve a satisfactory result, the patient can be placed on cardiopulmonary bypass and the valvotomy carried out under direct vision or the valve replaced.

On average, the mitral valve area is increased by 1 cm², with only 20% to 30% of patients requiring mitral valve replacement within 15 years. The hospital mortality rate is 1% to 2% in experienced centers. Marked symptomatic improvement occurs in most patients, and there is excellent long-term survival in patients selected with low echo scores.¹⁸⁰ Long-term follow-up has shown that the results are best if the operation is carried out before chronic AF and/or heart failure has occurred, and complication rates are higher when valves are calcified and/or severely thickened.

OPEN VALVOTOMY. Most surgeons now prefer to carry out direct-vision or open valvotomy. This operation is most frequently performed in patients with MS whose mitral valves are too distorted or calcified for BMV. Cardiopulmonary bypass is established and, to obtain a dry, quiet heart, body temperature is usually lowered, the heart is arrested, and the aorta is occluded intermittently. Thrombi are removed from the left atrium and its appendage, and the latter often is amputated to remove a potential source of postoperative emboli. The commissures are incised, and when necessary, fused chordae tendineae are separated, the underlying papillary muscle is split, and the valve leaflets are débrided of calcium. Mild or even moderate MR may be corrected using similar repair approaches as for primary MR. Left atrial and LV pressures are measured after bypass has been discontinued to confirm that the valvotomy has been effective. When it has not been effective, another attempt can be made. If repair is not possible—usually because of severe distortion and calcification of the valve and subvalvular apparatus, with accompanying MR that cannot be corrected—mitral valve replacement should be carried out. In patients with AF, a left atrial maze or AF ablation procedure typically is done at the time of surgery to increase the likelihood of maintaining long-term sinus rhythm. Open valvotomy is feasible and successful in more than 80% of patients referred for this procedure, with an operative mortality of 1%, rate of reoperation for mitral valve replacement of 0% to 16% at 36 to 53 months, and 10-year actuarial survival rates of 81% to 100%.

Restenosis after Valvotomy. Mitral valvotomy, whether percutaneous or operative and open or closed, is palliative rather than curative and, even when successful, there is some degree of residual mitral valve dysfunction. Because the valve is not normal postoperatively, turbulent flow usually persists in the paravalvular region, and the resultant trauma may play a role in restenosis. These changes are analogous to the gradual development of obstruction in a congenitally bicuspid aortic valve and are not usually the result of recurrent rheumatic fever. It is likely that the process of superimposed leaflet calcification and increased stiffness superimposed on the rheumatic valve is similar to the calcific changes seen in aortic valve stenosis.

On clinical grounds alone, based on the reappearance of symptoms, the incidence of restenosis has been estimated to range widely, from 2% to 60%. Recurrence of symptoms is usually not caused by restenosis but may be caused by one or more of the following conditions: (1) an inadequate first operation with residual stenosis; (2) increased severity of MR, either at operation or as a consequence of infective endocarditis; (3) progression of aortic valve disease; or (4) development of coronary artery disease. True restenosis occurs in less than 20% of patients who are followed for 10 years.¹⁵⁷

Thus, in properly selected patients, mitral valvotomy, however performed—percutaneous BMV, closed or open surgical valvotomy—is a low-risk procedure that results in a significant increase in the size of the mitral orifice and favorably alters the clinical course of an otherwise progressive disease. Pulmonary arterial pressure falls promptly and decisively when mitral obstruction is effectively relieved. Most patients maintain clinical improvement for 10 to 15 years of follow-up. When a second procedure is required because of symptomatic deterioration, the valve is usually calcified and more seriously deformed than at the time of the first operation, and adequate reconstruction may not be possible. Accordingly, mitral valve replacement often is necessary at that time.

Mitral Valve Replacement

Mitral valve replacement is recommended for symptomatic patients with severe MR when BMV or surgical mitral valve repair is not possible. Usually, mitral valve replacement is required for patients with

TABLE 63-8 Approaches to Mechanical Relief of Mitral Stenosis

APPROACH	ADVANTAGES	DISADVANTAGES
Closed surgical valvotomy	Inexpensive Relatively simple Good hemodynamic results in selected patients Good long-term outcome	No direct visualization of valve Only feasible with flexible, noncalcified valves Contraindicated with MR grade higher than 2+ Surgical procedure with general anesthesia
Open surgical valvotomy	Visualization of valve allows directed valvotomy Concurrent annuloplasty for MR is feasible	Best results with flexible, noncalcified valves Surgical procedure with general anesthesia
Valve replacement	Feasible in all patients regardless of extent of valve calcification or severity of MR	Surgical procedure with general anesthesia Effect of loss of annular-papillary muscle continuity on LV function Prosthetic valve Chronic anticoagulation
Balloon mitral valvotomy	Percutaneous approach Local anesthesia Good hemodynamic results in selected patients Good long-term outcome	No direct visualization of valve Only feasible with flexible noncalcified valves Contraindicated with MR grade higher than 2+

combined MS and moderate or severe MR, those with extensive commissural calcification, severe fibrosis, and subvalvular fusion, and those who have undergone previous valvotomy. The operative mortality rate for isolated mitral valve replacement ranges from 3% to 8% in most centers and averaged 6.04% in the large data base of 16,105 such operations for patients with MS and/or MR reported in the STS National Database (see Table 63-5). Prosthetic valves are associated with increased risk because of valve deterioration and chronic anticoagulation, so the threshold for operation should be higher in patients in whom preoperative evaluation suggests that mitral valve replacement may be required than in patients in whom valvotomy alone appears to be indicated.

Generally, a mechanical valve is preferred when mitral valve replacement for MS is necessary when AF is present because of the need for chronic anticoagulation. In patients younger than 65 years who are in sinus rhythm, a mechanical valve is reasonable because of the risk of tissue valve deterioration and likely need for a second operation in the future. However, some younger patients may choose a bioprosthetic valve for lifestyle considerations, despite the risk of valve deterioration. A bioprosthetic valve is appropriate in patients who cannot take warfarin and is reasonable in all patients older than 65 years.

Mitral valve replacement is indicated in patients with MS and mitral valve area smaller than 1.5 cm² in NYHA class III or IV whose valves are not suitable for valvotomy (see Fig. 63-24). Because the operative mortality risk may be high (10% to 20%) in patients in NYHA class IV, surgery should be carried out before patients reach this stage if possible. On the other hand, even such high-risk patients should not be denied this option unless they have comorbid conditions that preclude surgery or a satisfactory outcome.

FIGURE 63-28 Continuity of the mitral apparatus and the LV myocardium. MR may be caused by any condition that affects the leaflets or the structure and function of the left ventricle. Similarly, a surgical procedure that disrupts the mitral apparatus in an attempt to correct MR will have adverse effects on LV geometry, volume, and function. (From Otto CM: Evaluation and management of chronic mitral regurgitation. *N Engl J Med* 345:740, 2001.)

Mitral Regurgitation Causes and Pathology

The mitral valve apparatus involves the mitral leaflets, chordae tendineae, papillary muscles, and mitral annulus (see Fig. 63-28; Video 63-16). Abnormalities of any of these structures may cause MR.^{181,182} The major causes of MR include MVP, rheumatic heart disease, infective endocarditis, annular calcification, cardiomyopathy, and ischemic heart disease (see Table e63-4). Specific aspects of the MVP syndrome, the most important cause of significant MR in the United States, are discussed later. Less common causes of MR include collagen vascular diseases, trauma, the hypereosinophilic syndrome, carcinoid, and exposure to certain drugs.

The many potential causes of MR can be categorized by the mechanism of leaflet dysfunction as proposed by Carpentier (Fig. 63-29), because these mechanisms also determine the strategies for surgical correction.¹⁸² Leaflet motion is normal in type I, increased in type II, and restricted in type III (restricted opening in IIIa and restricted

closure in IIIb). In general, types II and IIIa usually are caused by primary disorders of the valve leaflets, whereas types I and IIIb often are caused by disorders of LV dysfunction, with LV and annular remodeling and secondary MR. The surgeon's view of the mitral valve in these four conditions is shown in Figure 63-30. For clinical purposes, MR is classified as *primary* (or degenerative) MR, caused by intrinsic disease of the mitral leaflets, and *secondary* MR, caused by diseases of the left ventricle and/or mitral annulus. Secondary MR is further classified as *ischemic* or *functional* (nonischemic), depending on the contribution of coronary artery disease to left ventricular myocardial dysfunction. These are two distinctly different disease conditions, with different pathophysiologies, outcomes, and management considerations.

Abnormalities of Valve Leaflets

MR caused by primary abnormalities of the valve leaflets occurs in many situations.^{182,183} MR in patients with chronic rheumatic heart

FIGURE 63-29 Pathophysiologic triad approach to MR and its multifactorial etiology. The mechanism of leaflet dysfunction defines the three types of MR. (From Castillo JG, Adams DH: *Mitral valve repair and replacement*. In Otto CM, Bonow RO [eds]: *Valvular Heart Disease: A Companion to Braunwald's Heart Disease*. 4th ed. Philadelphia, Saunders, 2013, pp 327-340.)

disease, in contrast with MS, is more frequent in men than in women. It is a consequence of shortening, rigidity, deformity, and retraction of one or both mitral valve cusps and is associated with shortening and fusion of the chordae tendineae and papillary muscles. MVP involves both leaflets and chordae and is usually associated with annular dilation. Infective endocarditis can cause MR by perforating valve leaflets (see Chapter 64); vegetations can prevent leaflet coaptation, and valvular retraction during the healing phase of endocarditis can cause MR. Destruction of the mitral valve leaflets can also occur in patients with penetrating and nonpenetrating trauma (see Chapter 72). MR associated with drug exposure also results from anatomic changes in the valve leaflets.

Abnormalities of the Mitral Annulus

DILATION. In a normal adult, the mitral annulus measures approximately 10 cm in circumference. It is soft and flexible, and contraction of the surrounding LV muscle during systole causes the annular constriction that contributes importantly to valve closure.¹⁵⁶ MR secondary to dilation of the mitral annulus can occur in any form of heart disease characterized by dilation of the left ventricle, especially

dilated cardiomyopathy.^{156,184} Increasing evidence suggests that chronic atrial fibrillation can lead to annular enlargement with subsequent MR.^{185,186} LV submitral aneurysm has been reported as a cause of annular MR in sub-Saharan Africa and appears to be caused by a congenital defect in the posterior portion of the annulus. In addition, primary diseases of the leaflets, such as myxomatous disease, are associated with annular dilation and abnormal annular motion, which may aggravate severity of MR.^{187,188}

CALCIFICATION. Idiopathic (degenerative) calcification of the mitral annulus is one of the most common cardiac abnormalities found at autopsy; in most hearts, it is of little functional consequence. However, when severe (see Fig. e15-10), it may be an important cause of MR and, in contrast to MR secondary to rheumatic fever, is more common in women than in men. The development of degenerative calcification of the mitral annulus shares common risk factors with atherosclerosis, including systemic hypertension, hypercholesterolemia, and diabetes. Hence, mitral annular calcification is associated with coronary and carotid atherosclerosis, as well as aortic valve calcification, and identifies patients at higher risk for cardiovascular morbidity and mortality. Annular calcification may also be

FIGURE 63-30 Valve lesions in MR. **A**, Severe annular dilation leading to type I dysfunction. **B**, Severe myxomatous changes with redundant, thick, and bulky segments in a patient with Barlow's disease and type II dysfunction. **C**, Rheumatic mitral valve disease with classic "fish mouth" appearance and type IIIA dysfunction. **D**, Ischemic mitral valve disease caused by severe tethering of the P3 scallop leading to type IIIB dysfunction. (From Castillo JG, Adams DH: *Mitral valve repair and replacement*. In Otto CM, Bonow RO [eds]: *Valvular Heart Disease: A Companion to Braunwald's Heart Disease*. 4th ed. Philadelphia, Saunders, 2013, pp 327-340.)

accelerated by an intrinsic defect in the fibrous skeleton of the heart, as in the Marfan and Hurler syndromes. In these two syndromes, the mitral annulus is not only calcified but dilated, further contributing to MR. The incidence of mitral annular calcification is also increased in patients who have chronic renal failure with secondary hyperparathyroidism. The annulus also may become thick, rigid, and calcified secondary to rheumatic involvement; when this process is severe, it also can interfere with valve closure.

With severe annular calcification, a rigid curved bar or ring of calcium encircles the mitral orifice, and calcific spurs may project into the adjacent LV myocardium. The calcification may immobilize the basal portion of the mitral leaflets, preventing their normal excursion in diastole and coaptation in systole, and aggravating the MR that results from loss of the normal sphincteric action of the mitral ring. Rarely, obstruction to LV filling may occur when severe calcification encroaches on or protrudes into the mitral orifice. In patients with severe calcification, the conduction system may be invaded by calcium, leading to atrioventricular and/or intraventricular conduction defects. Calcification of the aortic valve cusps is an associated finding in approximately 50% of patients with severe mitral annular calcification,^{160,161} but this rarely causes AS. Occasionally, calcific deposits extend into the coronary arteries.

Abnormalities of the Chordae Tendineae. Abnormalities of the chordae tendineae are important causes of MR (see Fig. 14-31). Lengthening and rupture of the chordae tendineae are cardinal features of the MVP syndrome (see Fig. 14-42). The chordae may be congenitally abnormal; rupture may be spontaneous (primary) or may occur as a consequence of infective endocarditis, trauma, rheumatic

fever or, rarely, osteogenesis imperfecta or relapsing polychondritis. In most patients, no cause for chordal rupture is apparent other than increased mechanical strain. Chordae to the posterior leaflet rupture more frequently than those to the anterior leaflet. Patients with idiopathic rupture of mitral chordae tendineae frequently exhibit pathologic fibrosis of the papillary muscles. It is possible that the dysfunction of the papillary muscles may cause stretching and ultimately rupture of the chordae tendineae. Chordal rupture also may result from acute LV dilation, regardless of the cause. Depending on the number of chordae involved in rupture and the rate at which rupture occurs, the resultant MR may be mild, moderate, or severe and acute, subacute, or chronic.

Involvement of the Papillary Muscles. Diseases of the LV papillary muscles are a frequent cause of MR. Because these muscles are perfused by the terminal portion of the coronary vascular bed, they are particularly vulnerable to ischemia, and any disturbance in coronary perfusion may result in papillary muscle dysfunction. When ischemia is transient, it results in temporary papillary muscle dysfunction and may cause transient episodes of MR that are sometimes associated with attacks of angina pectoris or pulmonary edema. When ischemia of papillary muscles is severe and prolonged, it causes papillary muscle dysfunction and scarring, as well as chronic MR. The posterior papillary muscle, which is supplied by the posterior descending branch of the right coronary artery, becomes ischemic and infarcted more frequently than the anterolateral papillary muscle; the latter is supplied by diagonal branches of the left anterior descending coronary artery and often by marginal branches from the left circumflex artery as well. Ischemia of the papillary muscles usually is caused by coronary atherosclerosis but also may occur in patients with severe anemia, shock, coronary arteritis of any cause, or an anomalous left coronary artery. MR occurs frequently in patients with healed myocardial infarcts and most frequently is caused by regional dysfunction

of the LV myocardium at the base of a papillary muscle, resulting in tethering of the mitral leaflets and incomplete leaflet coaptation.¹⁸⁹ Although necrosis of a papillary muscle is a frequent complication of myocardial infarction, frank rupture is far less common; the latter usually is fatal because of the extremely severe MR that it produces (see Chapter 52). However, rupture of one or two of the apical heads of a papillary muscle can result in a flail leaflet (see Fig. 14-30A) with a lesser degree of MR, and thus makes survival possible, usually after surgical therapy.

Various other disorders of the papillary muscles also may be responsible for the development of MR (see Chapters 22, 54, and 65). These disorders include congenital malposition of the muscles, absence of one papillary muscle, resulting in the so-called parachute mitral valve syndrome, and involvement or infiltration of the papillary muscles by a variety of processes, including abscesses, granulomas, neoplasms, amyloidosis, and sarcoidosis.

Left Ventricular Dysfunction. Ischemic LV dysfunction and dilated cardiomyopathy are important causative factors in the development of MR and represent the second leading cause of MR after MVP in the United States.¹⁸⁹ LV dilation of any cause including ischemia can alter the spatial relationships between the papillary muscles and chordae tendineae and thereby result in functional MR (see Fig. 63-27; see also Figs. 14-32B and 14-41).^{190,191}

Some degree of MR is found in approximately 30% of patients with coronary artery disease who are being considered for CABG. In most of these patients, MR develops from tethering of the posterior leaflet because of regional LV dysfunction. The outlook for the patient with ischemic MR is substantially worse than that for the patient with MR from other causes, because of the associated LV remodeling and systolic dysfunction. Other pathologic changes may include additional ischemic damage to the papillary muscles, dilation of the mitral valve ring, and/or loss of systolic annular contraction contributing further to MR. In most of these patients, MR is mild; however, any degree of MR is associated with a worse prognosis than in patients without MR.^{192,193} The incidence and severity of regurgitation vary inversely with the LV ejection fraction and directly with the LV end-systolic volume. MR occurs in approximately 20% of patients after acute myocardial infarction and, even when mild, is associated with a higher risk of adverse outcomes.^{189,192,193}

Other causes of MR, discussed in greater detail elsewhere, include obstructive HCM (see Chapter 66), the hyper eosinophilic syndrome, endomyocardial fibrosis, trauma affecting the leaflets and/or papillary muscles, Kawasaki disease, left atrial myxoma, and various congenital anomalies, including cleft anterior leaflet and ostium secundum atrial septal defect (see Chapters 62, 72, and 84).

Chronic Primary Mitral Regurgitation Pathophysiology

Because the regurgitant mitral orifice is functionally in parallel with the aortic valve, the impedance to ventricular emptying is reduced in patients with MR. Consequently, MR enhances LV emptying. Almost 50% of the regurgitant volume is ejected into the left atrium before the aortic valve opens. The volume of MR flow depends on a combination of the instantaneous size of the regurgitant orifice and the (reverse) pressure gradient between the left ventricle and left atrium.¹⁹⁴ Both the orifice size and pressure gradient are labile. LV systolic pressure, and therefore the LV–left atrial gradient, depends on systemic vascular resistance and, in patients in whom the mitral annulus has normal flexibility, the cross-sectional area of the mitral annulus may be altered by many interventions. Thus increase of preload and afterload and depression of contractility increase LV size and enlarge the mitral annulus, and thereby the regurgitant orifice. When LV size is reduced by treatment with positive inotropic agents, diuretics, and particularly vasodilators, the regurgitant orifice size decreases, and the volume of regurgitant flow declines, as reflected in the height of the *v* wave in the left atrial pressure pulse and in the intensity and duration of the systolic murmur. Conversely, LV dilation, regardless of cause, may increase MR.¹⁹⁵

LEFT VENTRICULAR COMPENSATION. The left ventricle initially compensates for the development of acute MR by emptying more completely and by increasing preload (i.e., by use of the Frank-Starling principle).¹⁹⁵ Because acute MR reduces late systolic LV pressure and radius, LV wall tension declines markedly (and

proportionately to a greater extent than LV pressure), permitting a reciprocal increase in the extent and velocity of myocardial fiber shortening, leading to a reduced end-systolic volume (Fig. 63-31). When MR, particularly severe MR, becomes chronic, the LV end-diastolic volume increases and the end-systolic volume returns to normal. By means of the Laplace principle, which states that myocardial wall tension is related to the product of intraventricular pressure and radius, the increased LV end-diastolic volume increases wall tension to normal or supranormal levels in the so-called chronic compensated stage of severe MR. The resultant increase in LV end-diastolic volume and mitral annular diameter may create a vicious circle in which MR leads to more MR. In patients with chronic MR, LV end-diastolic volume and mass are increased; that is, typical volume overload (eccentric) hypertrophy develops. However, the degree of hypertrophy is often not proportional to the degree of LV dilation, so the ratio of LV mass to end-diastolic volume may be less than normal. Nonetheless, the reduced afterload permits maintenance of ejection fraction in the normal to supranormal range. The reduced LV afterload allows a greater proportion of the contractile energy of the myocardium to be expended in shortening than in tension development, and explains how the left ventricle can adapt to the load imposed by MR.

The eccentric LV hypertrophy that accompanies the elevated end-diastolic volume of chronic MR is secondary to new sarcomeres laid down in series. A shift to the right (greater volume at any pressure) occurs in the LV diastolic pressure-volume curve in patients with chronic MR. With decompensation, chamber stiffness increases, raising the diastolic pressure at any volume.

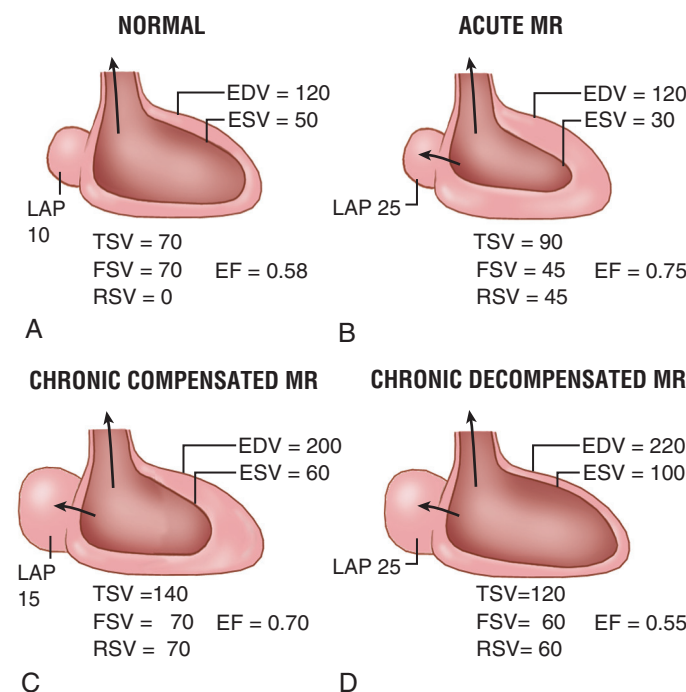

FIGURE 63-31 Three phases of MR are depicted and compared with normal physiology (A). B, In acute MR, an increase in preload and a decrease in afterload cause an increase in end-diastolic volume (EDV) and a decrease in end-systolic volume (ESV), producing an increase in total stroke volume (TSV). Forward stroke volume (FSV) is diminished, however, because 50% of the TSV regurgitates as the regurgitant stroke volume (RSV), resulting in an increase in left atrial pressure (LAP). C, In the chronic compensated phase, eccentric hypertrophy has developed and EDV is now increased substantially. Afterload has returned toward normal as the radius term of the Laplace relationship increases with the increase in EDV. Normal muscle function and a large increase in EDV permit a substantial increase in TSV from the acute phase. This, in turn, permits a normal FSV. Left atrial enlargement now accommodates the regurgitant volume at lower LAP. Ejection fraction (EF) remains greater than normal. D, In the chronic decompensated phase, muscle dysfunction has developed, impairing ejection fraction, diminishing both TSV and FSV. The EF, although still normal, has decreased to 0.55, and LAP is reelevated because less volume is ejected during systole, causing a higher ESV. (From Carabello BA: Progress in mitral and aortic regurgitation. *Curr Probl Cardiol* 28:553, 2003.)

In most patients with severe primary MR, compensation is maintained for years, but in some patients the prolonged hemodynamic overload ultimately leads to myocardial decompensation.^{194,195} End-systolic volume, preload, and afterload all increase, whereas ejection fraction and stroke volume decline. In such patients, there is evidence of neurohormonal activation and elevation of circulating proinflammatory cytokines. Plasma natriuretic peptide levels also increase in response to the volume load^{196,197}—more in patients with symptomatic decompensation.

Coronary flow rates may be increased in patients with severe MR, but the increases in myocardial oxygen consumption (MVO_2) are relatively modest compared with patients with AS and AR, because myocardial fiber shortening, which is elevated in patients with MR, is not one of the principal determinants of MVO_2 (see Chapter 21). One of these determinants, mean LV wall tension, may actually be reduced in patients with MR, whereas the other two, contractility and heart rate, may be little affected. Thus patients with MR have a low incidence of clinical manifestations of myocardial ischemia compared with the much higher incidence in those with AS and AR, conditions in which MVO_2 is greatly augmented.

ASSESSMENT OF MYOCARDIAL CONTRACTILITY IN MITRAL REGURGITATION. Because the ejection phase indices of myocardial contractility are inversely correlated with afterload, patients with early MR (with reduced LV afterload) often exhibit elevations in ejection phase indices of myocardial contractility, such as ejection fraction, fractional fiber shortening, and velocity of circumferential fiber shortening (VCF).^{35,195} Many patients ultimately develop symptoms because of elevated left atrial and pulmonary venous pressures related to the regurgitant volume and with no change in these ejection phase indices, which remain elevated. In other patients, however, major symptoms reflect serious contractile dysfunction, at which time ejection fraction, fractional shortening, and mean VCF have declined to low-normal or below-normal levels (see Fig. 63-31). As MR persists, the reduction in afterload, which increases myocardial fiber shortening and the aforementioned ejection phase indices, is opposed by the impairment of myocardial function characteristic of severe chronic diastolic overload. However, even in patients with overt heart failure secondary to MR, the ejection fraction and fractional shortening may be only modestly reduced. Therefore, values in the low-normal range for the ejection phase indices of myocardial performance in patients with chronic MR may actually reflect impaired myocardial function, whereas moderately reduced values (e.g., ejection fraction 40% to 50%) generally signify severe, often irreversible, impairment of contractility, identifying patients who may do poorly after surgical correction of the MR (see Fig. e63-3). An ejection fraction of less than 35% in patients with severe MR usually represents advanced myocardial dysfunction; such patients are high operative risks and may not experience satisfactory improvement after mitral valve replacement.

END-SYSTOLIC VOLUME. Preoperative myocardial contractility is an important determinant of the risk of operative death, cardiac failure perioperatively, and postoperative level of LV function. It is not surprising, therefore, that the end-systolic pressure-volume (or stress-dimension) relationship has emerged as a useful index for evaluating LV function in patients with MR. The simple measurement of end-systolic volume or diameter has been found to be a useful predictor of function and survival after mitral valve surgery.^{194,195,198} A preoperative LV end-systolic diameter that exceeds 40 mm identifies a patient with a high likelihood of impaired LV systolic function after surgery.^{1,199}

HEMODYNAMICS. Effective (forward) cardiac output usually is depressed in severely symptomatic patients with MR, whereas total LV output (the sum of forward and regurgitant flow) usually is elevated until late in the patient's course. The cardiac output achieved during exercise, not the regurgitant volume, is the principal determinant of functional capacity. The atrial contraction *a* wave in the left atrial pressure pulse usually is not as prominent in MR as in MS, but the *v* wave is characteristically much taller (see Chapter 19) because it is inscribed during ventricular systole, when the left atrium is being filled with blood from the pulmonary veins and from the left ventricle. Occasionally, backward transmission of the tall *v* wave into the

pulmonary arterial bed may result in an early diastolic pulmonary arterial *v* wave (see Fig. e63-4). In patients with isolated MR, the *y* descent in the pulmonary capillary pressure pulse is particularly rapid because the distended left atrium empties rapidly during early diastole. However, in patients with combined MS and MR, the *y* descent is gradual. Although a left atrioventricular pressure gradient persisting throughout diastole signifies the presence of significant associated MS, a brief early diastolic gradient may occur in patients with isolated severe MR as a result of the rapid flow of blood across a normal-sized mitral orifice early in diastole, often accompanied by an early diastolic murmur at the apex.

LEFT ATRIAL COMPLIANCE. The compliance of the left atrium (and pulmonary venous bed) is an important determinant of the hemodynamic and clinical picture in patients with severe MR. Three major subgroups of patients with severe MR based on left atrial compliance have been identified and are characterized as follows.

NORMAL OR REDUCED COMPLIANCE. In the subgroup of patients with normal or reduced compliance, findings include little enlargement of the left atrium but marked elevation of the mean left atrial pressure, particularly of the *v* wave, and pulmonary congestion is a prominent symptom. Severe MR usually develops acutely, as occurs with rupture of the chordae tendineae, infarction of one of the heads of a papillary muscle, or perforation of a mitral leaflet occurring as a consequence of trauma or endocarditis. In patients with acute MR, the left atrium initially operates on the steep portion of its pressure-volume curve, with a marked rise in pressure for a small increase in volume. Sinus rhythm usually is present; after weeks or a few months, the left atrial wall becomes hypertrophied and is capable of contracting vigorously, facilitating LV filling. The thicker atrium is less compliant than normal, which further increases the height of the *v* wave. Thickening of the walls of the pulmonary veins and proliferative changes in the pulmonary arteries, as well as marked elevations in pulmonary vascular resistance and pulmonary artery pressure, usually develop over the course of 6 to 12 months after the onset of acute severe MR.

MARKEDLY INCREASED COMPLIANCE. At the opposite end of the spectrum from patients in the first group are those with markedly increased compliance, characterized by severe longstanding MR with massive enlargement of the left atrium and normal or only slightly elevated left atrial pressure. The atrial wall contains only a small remnant of muscle surrounded by fibrous tissue. Longstanding MR in these patients has altered the physical properties of the left atrial wall and thereby displaced the atrial pressure-volume curve to the right, allowing a normal or almost normal pressure to exist in a greatly enlarged left atrium. Pulmonary arterial pressure and pulmonary vascular resistance may be normal or only slightly elevated at rest. AF and a low cardiac output are almost invariably present.

MODERATELY INCREASED COMPLIANCE. The most common subgroup consists of patients with moderately increased compliance, between the ends of the spectrum represented by the first and second groups. These patients have severe chronic MR and exhibit variable degrees of enlargement of the left atrium, associated with significant elevation of the left atrial pressure, and these two factors (in association with age) determine the likelihood that AF will ensue.

Clinical Presentation

The clinical stages of primary chronic degenerative MR are indicated in Table 63-9, demonstrating the progressive nature of the disease.

Symptoms. The nature and severity of symptoms in patients with chronic MR are functions of a combination of interrelated factors, including the severity of MR, rate of its progression, level of left atrial, pulmonary venous, and pulmonary arterial pressure, presence of episodic or chronic atrial tachyarrhythmias, and presence of associated valvular, myocardial, or coronary artery disease. Symptoms may occur with preserved LV contractile function in patients with chronic MR who have severely elevated pulmonary venous pressures or AF. In other patients, symptoms herald LV decompensation. In patients with rheumatic MR, the time interval between the initial attack of rheumatic fever and development of symptoms tends to be longer than in those with MS, and often exceeds two decades. Hemoptysis and systemic embolization are less common in patients with isolated or

FIGURE e63-3 Late survival of patients after surgical correction of MR. Patients are subdivided on the basis of the preoperative echocardiographic ejection fraction (EF). (From Enriquez-Sarano M, Tajik AJ, Schaff HV, et al: Echocardiographic prediction of survival after surgical correction of organic mitral regurgitation. *Circulation* 90:833, 1994.)

FIGURE e63-4 Hemodynamic tracings in a 45-year-old woman with acute mitral regurgitation from bacterial endocarditis. **A**, Pulmonary artery pressure. **B**, Simultaneous left ventricular diastolic pressure (LVDP) and pulmonary capillary wedge pressure (PCWP). The PCWP tracing demonstrates a markedly elevated v wave (arrowhead, **B**) that transmits to the pulmonary artery pressure (arrowhead, **A**). (Modified from Wisse B, Sniderman AD: Severe mitral regurgitation. *N Engl J Med* 343:1386, 2000.)

TABLE 63-9 Stages of Chronic Primary Mitral Regurgitation

GRADE	DEFINITION	VALVE ANATOMY	VALVE HEMODYNAMICS	HEMODYNAMIC CONSEQUENCES	SYMPTOMS
A	At risk for MR	Mild mitral valve prolapse with normal coaptation Mild valve thickening and leaflet restriction	No MR jet or small central jet area <20% LA on Doppler Small vena contracta <0.3 cm	None	None
B	Progressive MR	Severe mitral valve prolapse with normal coaptation Rheumatic valve changes with leaflet restriction and loss of central coaptation Previous IE	Central jet MR 20%-40% LA or late systolic eccentric jet MR Vena contracta <0.7 cm Regurgitant volume <60 mL Regurgitant fraction <50% ERO <0.40 cm ² Angiographic grade 1-2+	Mild LA enlargement No LV enlargement Normal pulmonary pressure	None
C	Asymptomatic severe MR	Severe mitral valve prolapse with loss of coaptation or flail leaflet Rheumatic valve changes with leaflet restriction and loss of central coaptation Previous IE Thickening of leaflets with radiation heart disease	Central jet MR >40% LA or holosystolic eccentric jet MR Vena contracta ≥0.7 cm Regurgitant volume ≥60 mL Regurgitant fraction ≥50% ERO ≥0.40 cm ² Angiographic grade 3-4+	Moderate or severe LA enlargement LV enlargement Pulmonary hypertension may be present at rest or with exercise C1: LVEF >60% and LVESD <40 mm C2: LVEF ≤60% and LVESD ≥40 mm	None
D	Symptomatic severe MR	Severe mitral valve prolapse with loss of coaptation or flail leaflet Rheumatic valve changes with leaflet restriction and loss of central coaptation Previous IE Thickening of leaflets with radiation heart disease	Central jet MR >40% LA or holosystolic eccentric jet MR Vena contracta ≥0.7 cm Regurgitant volume ≥60 mL Regurgitant fraction ≥50% ERO ≥0.40 cm ² Angiographic grade 3-4+	Moderate or severe LA enlargement LV enlargement Pulmonary hypertension present	Decreased exercise tolerance Exertional dyspnea

*Several valve hemodynamic criteria are provided for assessment of MR severity, but not all criteria for each category will be present in each patient. Classification of MR severity as mild, moderate, or severe depends on data quality and integration of these parameters in conjunction with other clinical evidence.

ERO = effective regurgitant orifice; IE = infective endocarditis; LA = left atrium; LVEF = left ventricular ejection fraction; LVESD = left ventricular end-systolic dimension. From Nishimura RA, Otto CM, Bonow RO, et al: 2014 AHA/ACC guideline for the management of patients with valvular heart disease: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 63:e57, 2014.

predominant MR than in those with MS. The development of AF affects the course adversely but perhaps not as dramatically as in MS. Conversely, chronic weakness and fatigue secondary to a low cardiac output are more prominent features in MR.

Most patients with MR of rheumatic origin have only mild disability, unless regurgitation progresses as a result of chronic rheumatic activity, infective endocarditis, or rupture of the chordae tendineae. However, the indolent course of MR may be deceptive. By the time that symptoms secondary to a reduced cardiac output and/or pulmonary congestion become apparent, serious and sometimes even irreversible LV dysfunction may have developed.

In patients with severe chronic MR who have a greatly enlarged left atrium and relatively mild left atrial hypertension (patients with increased left atrial compliance), pulmonary vascular resistance does not usually rise markedly. Instead, the major symptoms, fatigue and exhaustion, are related to the depressed cardiac output. Right-sided heart failure, characterized by congestive hepatomegaly, edema, and ascites, may be prominent in patients with acute MR, elevated pulmonary vascular resistance, and pulmonary hypertension. Angina pectoris is rare unless coronary artery disease coexists.

Physical Examination. Palpation of the arterial pulse is helpful in differentiating AS from MR, both of which may produce a prominent systolic murmur at the base of the heart and apex (see Chapter 11). The carotid arterial upstroke is sharp in severe MR and delayed in AS; the volume of the pulse may be normal or reduced in the presence of heart failure. The cardiac impulse, like the arterial pulse, is brisk and hyperdynamic. It is displaced to the left, and a prominent LV filling wave is frequently palpable. Systolic expansion of the enlarged left atrium may result in a late systolic thrust in the parasternal region, which may be confused with RV enlargement.

Auscultation. When chronic severe MR is caused by defective valve leaflets, S_1 , produced by mitral valve closure, is usually diminished. Wide splitting of S_2 is common and results from the shortening of LV ejection and an earlier A_2 as a consequence of reduced resistance to

LV ejection. In patients with severe pulmonary hypertension, P_2 is louder than A_2 . The abnormal increase in the flow rate across the mitral orifice during the rapid filling phase is often associated with a S_3 , which should not be interpreted as a feature of heart failure in these patients, and this may be accompanied by a brief diastolic rumble.

The systolic murmur is the most prominent physical finding; it must be differentiated from the systolic murmur of AS, TR, and ventricular septal defect. In most patients with severe MR, the systolic murmur commences immediately after the soft S_1 and continues beyond and may obscure the A_2 because of the persisting pressure difference between the left ventricle and left atrium after aortic valve closure. The holosystolic murmur of chronic MR is usually constant in intensity, blowing, high-pitched, and loudest at the apex, with frequent radiation to the left axilla and left infrascapular area. Radiation toward the sternum or aortic area, however, may occur with abnormalities of the posterior leaflet and is particularly common in patients with MVP involving this leaflet. The murmur shows little change, even in the presence of large beat-to-beat variations of LV stroke volume, as in AF. This finding contrasts with that in most midsystolic (ejection) murmurs, such as in AS, which vary greatly in intensity with stroke volume and therefore with the duration of diastole. Little correlation has been found between the intensity of the systolic murmur and severity of MR. In patients with severe MR caused by LV dilation, acute myocardial infarction, or paraprothestic valvular regurgitation, or in those who have marked emphysema, obesity, chest deformity, or a prosthetic heart valve, the systolic murmur may be barely audible or even absent, a condition referred to as silent MR.

The murmur of MR may be holosystolic, late systolic, or early systolic. When the murmur is confined to late systole, the regurgitation usually is secondary to MVP or to papillary muscle dysfunction and is not severe. These causes of MR frequently are associated with a normal S_1 because initial closure of the mitral valve cusps may be unimpaired. The late systolic murmur of papillary muscle dysfunction

is particularly variable; it may become accentuated or holosystolic during acute myocardial ischemia and often disappears when ischemia is relieved. A midsystolic click preceding a mid- to late systolic murmur, and the response of that murmur to a number of maneuvers, helps establish the diagnosis of MVP (discussed subsequently). Early systolic murmurs are typical of acute MR. When the left atrial *v* wave is markedly elevated in acute MR, the murmur may diminish or disappear in late systole as the reverse pressure gradient declines. As noted, a short, low-pitched diastolic murmur following S_3 may be audible in patients with severe MR, even without accompanying MS.

Dynamic Auscultation. The holosystolic murmur of MR varies little during respiration. However, sudden standing usually diminishes the murmur, whereas squatting augments it. The late systolic murmur of MVP behaves in the opposite direction, decreasing in duration with squatting and increasing in duration with standing. The holosystolic MR murmur is reduced during the strain of the Valsalva maneuver and shows a left-sided response (i.e., a transient overshoot that occurs six to eight beats after release of the strain). The murmur of MR usually is intensified by isometric exercise, differentiating it from the systolic murmurs of valvular AS and obstructive HCM, both of which are reduced by this intervention. The murmur of MR caused by LV dilation decreases in intensity and duration after effective therapy with cardiac glycosides, diuretics, rest, and particularly vasodilators.

Differential Diagnosis

The holosystolic murmur of MR resembles that produced by a ventricular septal defect. However, the latter is usually loudest at the sternal border rather than the apex and is often accompanied by a parasternal, rather than an apical, thrill. The murmur of MR may also be confused with that of TR, but the latter is usually heard best along the left sternal border, is augmented during inspiration, and is accompanied by a prominent *v* wave and *y* descent in the jugular venous pulse.

When the chordae tendineae to the posterior leaflet of the mitral valve rupture, the regurgitant jet is often directed anteriorly, so that it impinges on the atrial septum adjacent to the aortic root and causes a systolic murmur that is most prominent at the base of the heart. This murmur can be confused with that of AS. On the other hand, when the chordae tendineae to the anterior leaflet rupture, the jet usually is directed to the posterior wall of the left atrium and the murmur may be transmitted to the spine or even the top of the head.

Patients with rheumatic disease of the mitral valve exhibit a spectrum of abnormalities, ranging from pure MS to pure MR. The presence of a S_3 , a rapid LV filling wave and prominent LV impulse on palpation, and a soft S_1 all favor predominant MR. By contrast, an accentuated S_1 , a prominent OS with a short A₂-OS interval, and a soft, short systolic murmur all indicate predominant MS. Elucidation of the predominant valvular lesion may be complicated by the presence of a holosystolic murmur of TR in patients with pure MS and pulmonary hypertension; this murmur may sometimes be heard at the apex when the right ventricle is greatly enlarged and may therefore be mistaken for the murmur of MR.

Echocardiography

Echocardiography plays a central role in the diagnosis of MR, in determining its cause and potential for repair, and in quantifying its severity (see Chapter 14). In patients with severe
